ELSEVIER

Principles and Practice of Pediatric Infectious Diseases

FIFTH EDITION

Editor

SARAH S. LONG, MD

Professor of Pediatrics
Drexel University College of Medicine
Chief, Section of Infectious Diseases
St. Christopher's Hospital for Children
Philadelphia, Pennsylvania

Associate Editors

CHARLES G. PROBER, MD

Professor of Pediatrics, Microbiology, and Immunology
Senior Associate Dean for Medical Education
Stanford University School of Medicine
Stanford, California

MARC FISCHER, MD, MPH

Medical Epidemiologist
Arboviral Diseases Branch
Centers for Disease Control and Prevention
Fort Collins, Colorado

Part I Understanding, Controlling, and Preventing Infectious Diseases

A Epidemiology and Control of Infectious Diseases

1 Principles of Epidemiology and Public Health

Descriptive Epidemiology

Analytic Epidemiology

Vaccine Efficacy Studies

Disease Control and Public Health Policy

Evaluating the Medical Literature

Acknowledgments

References

2 Pediatric Healthcare Epidemiology

Risk Factors for Healthcare-Associated Infections in Children

Transmission

Pathogens

Prevention Programs

References

3 Infections Associated With Group Childcare

Childcare Settings

Epidemiology and Etiology of Infections

Vaccine-Preventable Diseases

Infections Associated With Animals

Infectious Diseases in Adults

Economic Impact of Group Childcare Illness

Prevention

References

4 Infectious Diseases in Refugee and Internationally Adopted Children

Guidelines for Evaluation

Preventive Measures

References

B Prevention of Infectious Diseases

5 Passive Immunization

Immune Globulin (Human)

Specific Immune Globulins for Intramuscular Administration

Immune Globulin Intravenous (Human)

Specific Immune Globulins for Intravenous Administration

Monoclonal Antibodies

Immunoglobulin Products Prepared From Animal Plasma

Adverse Reactions to Immune Globulins Prepared From Human Plasma

Product Shortages

The Future

References

6 Active Immunization

Immunization and Vaccines: Overview

Vaccine Development, Licensure, and Approval

Principles of Immunization Programs

Routine Childhood and Adolescent Vaccines

Selected Other Vaccines That Can Be Used in Children and Adolescents

Sources of Information on Vaccines

References

7 Antimicrobial Chemoprophylaxis

General Principles

Chemoprophylaxis in Healthy Children

Chemoprophylaxis for Surgical Procedures and Trauma

Chemoprophylaxis in Special Situations and in Children With Conditions Predisposing to Infection

References

8 Protection of Travelers

Preparation for Travel

Malaria

Travelers' Diarrhea

Emerging Infectious Diseases

Immunocompromised Travelers

Return From Travel

References

C Host Defenses Against Infectious Diseases

---

9 Immunologic Development and Susceptibility to Infection

Innate Immune Response

Adaptive Immune Response

Interrelationships and the Future

- References

10 Fever and the Inflammatory Response

- Fever
- Inflammatory Response
- References

Part II Clinical Syndromes and Cardinal Features of Infectious Diseases: Approach to Diagnosis and Initial Management

A Septicemia, Toxin, and Inflammation-Mediated Syndromes

---

11 The Systemic Inflammatory Response Syndrome (SIRS), Sepsis, and Septic Shock

- Definitions
- Etiology
- Pathophysiology
- Clinical and Laboratory Findings
- Management
- Future Considerations
- References

12 Hemophagocytic Lymphohistiocytosis and Macrophage Activation Syndrome

- Hemophagocytic Lymphohistiocytosis

Etiology and Incidence

Pathogenesis

Clinical and Radiologic Features

Laboratory and Pathologic Findings

Diagnosis and Differential Diagnosis

Treatment

Prognosis

Macrophage Activation Syndrome

References

B Cardinal Symptom Complexes

---

13 Mucocutaneous Symptom Complexes

Specific Distinguishing Characteristics

Diagnosis and Empiric Therapy

References

14 Fever Without Localizing Signs

Etiologic Agents

Epidemiology

Laboratory Findings and Diagnosis

Management

References

15 Prolonged, Recurrent, and Periodic Fever Syndromes

Fever of Unknown Origin

Prolonged Insignificant Fever, Prolonged Illness With Resolved Fever, and Fatigue of Deconditioning

Recurrent Fever and Periodic Fever Syndromes

References

16 Lymphatic System and Generalized Lymphadenopathy

Anatomy and Function of Lymphoid Tissue

Developmental Changes

Characteristics of Lymphadenopathy

Pathogenesis of Lymphadenopathy and Lymphadenitis

Histopathology of Lymphadenitis

Lymphocutaneous and Oculoglandular Syndrome

Infectious Causes of Generalized Lymphadenopathy

Other Causes of Generalized Lymphadenopathy

References

17 Cervical Lymphadenitis and Neck Infections

Epidemiology

Lymphatic Flow and Fascial Spaces of the Head and Neck

Oculoglandular Syndrome of Parinaud

Infectious Causes of Lymphadenitis

Noninfectious Causes of Lymphadenopathy

Neck Masses Not Involving Lymph Nodes

Diagnostic Approach to Cervical Lymphadenopathy

Management

- Complications
- Acknowledgment
- References

18 Mediastinal and Hilar Lymphadenopathy

- Anatomy of the Mediastinum
- Lymphatic Drainage of the Lungs and Pleura
- Epidemiology
- Characteristics of Lymphadenopathy
- Clinical Manifestations
- Diagnosis
- Infectious Causes
- Noninfectious Causes
- Diagnostic Approach
- References

19 Abdominal and Retroperitoneal Lymphadenopathy

- Epidemiology and Differential Diagnosis
- Diagnostic Tests
- Therapy
- References

20 Localized Lymphadenitis, Lymphadenopathy, and Lymphangitis

- Lymphadenopathy and Lymphadenitis
- Lymphangitis

References

21 Respiratory Tract Symptom Complexes

Mucopurulent Rhinorrhea

Stridor

Cough

Tachypnea and Other Signs of Lower Respiratory Tract Disorders

Differentiating Features of Pneumonia

Hemoptysis

References

22 Abdominal Symptom Complexes

Acute Abdominal Pain

Chronic or Recurrent Abdominal Pain

Acknowledgments

References

23 Neurologic Symptom Complexes

Headache

Altered Mental Status

Ataxia

Hypotonia and Weakness

References

24 Musculoskeletal Symptom Complexes

History

Physical Examination

Laboratory Evaluation and Imaging

Limb Pain

Back Pain

Chest Pain

References

C Oral Infections and Upper and Middle Respiratory Tract Infections

---

25 Infections of the Oral Cavity

Odontogenic Infections

Mucosal Infections

Complications of Odontogenic and Mucosal Infections

Infections of the Salivary Gland

Osteomyelitis

References

26 The Common Cold

Etiology

Epidemiology

Pathogenesis

Clinical Manifestations

Differential Diagnosis

Clinical Approach

Management

Complications

Recent Advances

Acknowledgements

References

27 Pharyngitis

Etiology

Epidemiology

Clinical Manifestations

Diagnosis

Treatment

Complications

References

28 Infections of the Upper and Middle Airways

Peritonsillar Abscess

Retropharyngeal Abscess

Parapharyngeal Abscess

Lemierre Syndrome

Acute Epiglottitis

Croup

Acute Laryngitis

Bacterial Tracheitis

Acute Bronchitis

Acknowledgements

References

29 Otitis Media

Acute Otitis Media

Otitis Media With Effusion

References

30 Otitis Externa and Necrotizing Otitis Externa

Otitis Externa

Necrotizing Otitis Externa

References

31 Mastoiditis

Acute Mastoiditis

Chronic Mastoiditis

References

32 Sinusitis

Pathogenesis

Clinical Manifestations

Diagnostic Methods

Microbiology

Medical Management

Surgical Management

References

D Lower Respiratory Tract Infections

33 Bronchiolitis
- Etiologic Agents
- Epidemiology
- Pathogenesis and Pathologic Findings
- Clinical Manifestations
- Diagnosis
- Management
- Prognosis, Complications, and Sequelae
- Prevention
- References

34 Acute Pneumonia and Its Complications
- Acute Pneumonia
- Acute Complicated Pneumonia
- Acknowledgment
- References

35 Persistent and Recurrent Pneumonia
- Persistent or Progressive Pneumonia at a Single Site
- Persistent or Recurrent Pneumonia Not Confined to a Single Site
- Acknowledgments
- References

36 Pneumonia in the Immunocompromised Host

- Etiologic Agents and Epidemiology
- Pathogenesis and Pathologic Findings
- Clinical Diagnosis and Radiographic Manifestations
- Management and Therapy
- Prevention
- References

E Cardiac and Vascular Infections

37 Endocarditis and Other Intravascular Infections
- Infective Endocarditis
- Other Endocarditis-Like Intravascular Infections
- References

38 Myocarditis
- Etiology
- Epidemiology
- Pathophysiology
- Clinical Manifestations
- Differential Diagnosis
- Laboratory Findings and Diagnosis
- Management
- Complications
- Prevention
- References

39 Pericarditis

Etiology

Epidemiology

Pathogenesis

Clinical Manifestations

Differential Diagnosis

Laboratory Findings and Diagnosis

Management

Complications

Prognosis

References

F Central Nervous System Infections

---

40 Acute Bacterial Meningitis Beyond the Neonatal Period

Etiologic Agents and Epidemiology

Pathophysiology

Clinical Presentation

Laboratory Findings and Diagnosis

Management

Meningitis Due to Unusual Organisms

Supportive Care

Adjunctive Therapy

Prognosis

Prevention

References

41 Chronic Meningitis

- Etiology and Epidemiology
- Main Features of Agents Causing Chronic Meningitis
- Evaluation
- Empiric Therapy
- References

42 Recurrent Meningitis

- Etiologic Agents
- Epidemiology
- Pathogenesis
- Clinical Manifestations
- Diagnosis
- Treatment
- Prevention and Prophylaxis
- References

43 Aseptic and Viral Meningitis

- Etiologic Agents and Epidemiology
- Pathogenesis and Pathology
- Clinical Manifestations
- Differential Diagnosis
- Laboratory Findings and Diagnosis
- Management and Empiric and Definitive Therapy

Complications, Prognosis, and Sequelae

Prevention

44 Encephalitis

Etiologic Agents and Epidemiology

Pathogenesis

Clinical Manifestations and Differential Diagnosis

Special Hosts

Clinical Approach

Laboratory Findings

Management

Complications and Prognosis

Progress in Treatment and Prevention

References

45 Parainfectious and Postinfectious Neurologic Syndromes

Cranial Nerve Palsies

Cerebellitis

Acute Disseminated Encephalomyelitis

Transverse Myelitis

Acute Inflammatory Demyelinating Polyradiculoneuropathy (Guillain–Barré Syndrome)

Acute Flaccid Myelitis

References

46 Focal Suppurative Infections of the Nervous System

- Etiology
- Epidemiology
- Pathogenesis
- Clinical Manifestations
- Differential Diagnosis
- Laboratory Findings and Diagnosis
- Management
- Complications and Prognosis
- References

47 Eosinophilic Meningitis

- Infectious Causes
- Diagnosis and Treatment
- References

G Genitourinary Tract Infections

---

48 Urinary Tract Infections, Renal Abscess, and Other Complex Renal Infections

- Etiologic Agents
- Epidemiology
- Definitions
- Pathogenesis
- Risk Factors for Bacteruria and Renal Damage

Clinical Manifestations

Laboratory Findings

Management

Complications and Sequelae

Complex Urinary Tract Infections: Imaging Evaluation

Special Considerations

References

49 Sexually Transmitted Infection Syndromes

Genitourinary Syndromes

Pharyngeal Syndromes

Dermatologic Syndromes

References

50 Skin and Mucous Membrane Infections and Inguinal Lymphadenopathy

Inguinal Lymphadenopathy With Genital Ulcers

Inguinal Lymphadenopathy Without Genital Ulcers

Genital Dermatosis

References

51 Urethritis, Vulvovaginitis, and Cervicitis

Urethritis

Vulvovaginitis

Cervicitis

References

52 Pelvic Inflammatory Disease

Epidemiology

Etiologic Agents

Pathogenesis and Pathologic Findings

Diagnosis

Laboratory Findings and Diagnosis

Management

Complications and Sequelae

Prevention

References

53 Epididymitis, Orchitis, and Prostatitis

Epididymitis

Orchitis

Prostatitis

References

54 Infectious Diseases Associated With Child Abuse

Medical Evaluation

Infectious Agents

References

H Gastrointestinal Tract Infections and Intoxications

---

55 Approach to the Diagnosis and Management of Gastrointestinal Tract Infections

Epidemiology

Pathogenesis

Clinical Manifestations

Considerations of The Host and Exposures

Diagnosis

Treatment

Prevention

Acknowledgments

References

56 Viral Gastroenteritis

Etiologic Agents

Epidemiology

Pathogenesis

Clinical Manifestations

Diagnosis

Treatment

Prevention

57 Inflammatory Enteritis

Classification

Principal Etiologic Agents

Epidemiology

Pathogenesis

Diagnostic Evaluation
Inflammatory Enteritis in the Immunocompromised Host
Management
References

58 Necrotizing Enterocolitis

Epidemiology
Pathologic Findings and Pathogenesis
Clinical Manifestations, Differential Diagnosis, and Clinical Approach
Management
Prognosis and Complications
Advances in Understanding of Pathophysiology
Prevention
Acknowledgment
References

59 Enteric Diseases Transmitted Through Food, Water, and Zoonotic Exposures

Epidemiology
Pathogenesis and Clinical Syndromes
Enteric Disease Surveillance and Outbreak Detection
Diagnosis
Management
Complications
Prevention
References

I Intra-Abdominal Infections

60 Acute Hepatitis

Approach to Evaluation and Diagnosis

Infectious Causes

Anatomic Causes

Autoimmune Causes

Metabolic Causes

Toxins and Medications

Tumors

Idiopathic Causes

References

61 Chronic Hepatitis

Approach to Evaluation

Etiologic Factors

References

62 Granulomatous Hepatitis

Pathogenesis and Pathologic Findings

Clinical Manifestations and Differential Diagnosis

Diagnosis

Management and Outcome

63 Acute Pancreatitis

Pathogenesis

Clinical Manifestations

Diagnosis

Differential Diagnosis

Treatment

Clinical Course

References

64 Cholecystitis and Cholangitis

Pathogenesis

Etiology

Clinical and Laboratory Features

Diagnosis

Management

Complications

References

65 Peritonitis

Epidemiology

Pathophysiology

Etiology

Clinical Presentation

Diagnosis

Management

Complications and Prognosis

Prevention

References

66 Appendicitis

Epidemiology

Pathogenesis

Etiology

Clinical Manifestations, Differential Diagnosis, and Laboratory Testing

Diagnostic Imaging and Scoring Systems

Management

Complicated Appendicitis

References

67 Intra-Abdominal, Visceral, and Retroperitoneal Abscesses

Intra-Abdominal Abscesses

Visceral Abscesses

Retroperitoneal Abscesses

References

J Skin and Soft Tissue Infections

---

68 Superficial Bacterial Skin Infections and Cellulitis

Superficial Infections

Adnexal and Follicular Infections

Hand and Nail Infections

Ulcerative Infections

Soft Tissue Infections

References

69 Erythematous Macules and Papules

Approach

Etiologic Agents, Epidemiology, and Pathogenesis

References

70 Vesicles and Bullae

Etiology and Clinical Manifestations

Diagnosis

Acknowledgment

References

71 Purpura

Types of Purpuric Lesions and Pathogenesis

Causes of Purpura

References

72 Urticaria and Erythema Multiforme

Urticaria

Erythema Multiforme

References

73 Papules, Nodules, and Ulcers

Molluscum Contagiosum
Erythema Nodosum
Gianotti-Crosti Syndrome
Other Exanthematous Infections
Autosensitization Reaction
References

74 Subcutaneous Tissue Infections and Abscesses
Etiology
Abscesses
Necrotizing Soft Tissue Infections
References

75 Myositis, Pyomyositis, and Necrotizing Fasciitis
Myositis
Pyomyositis
Necrotizing Fasciitis
Pathogenesis
Diagnosis
Treatment
Acknowledgments
References

K Bone and Joint Infections

---

76 Osteomyelitis

Acute Hematogenous Osteomyelitis

Special Clinical Situations

Osteomyelitis Due to Unusual Organisms

Nonhematogenous Osteomyelitis

Puncture Wound Osteochondritis of the Foot

Chronic Recurrent Multifocal Osteomyelitis

Chronic Osteomyelitis

References

77 Infectious and Inflammatory Arthritis

Infectious Arthritis

Special Situations and Pathogens

Reactive Arthritis

References

78 Diskitis

Epidemiology and Etiology

Pathogenesis and Pathologic Findings

Clinical Manifestations

Differential Diagnosis

Diagnosis

Management

Outcome

85 Preseptal and Orbital Infections

Differential Diagnosis
Pathogenesis
Preseptal Infections
Orbital Infection
References

M Infections Related to Trauma

---

86 Infection Following Trauma
Pathogenesis
General Principles of Management
Skin and Soft Tissue Trauma
Abdominal Trauma
Head Trauma
Fractures
Puncture Wounds
Thoracic Trauma
References

87 Infection Following Burns
Burn Wound Infection
Other Infections
Treatment
Management of Outpatients
Prevention

- Acknowledgments
- References

88 Infection Following Bites

- Etiologic Agents
- Epidemiology
- Pathogenesis
- Clinical Manifestations, Differential Diagnosis, and Clinical Approach
- Laboratory Findings and Diagnosis
- Management and Presumptive Therapy
- Empiric Management When Infection Occurs
- Complications
- Prognosis and Sequelae
- Prevention
- References

89 Infections Related to Pets and Exotic Animals

- Pet Exposures
- Categories of Pets
- Diseases (Zoonoses) Associated With Nontraditional Pets
- Diseases Associated With Animals in Public Settings
- Rabies
- Injuries and Allergies
- Reportable Diseases Acquired From Nontraditional Pets and Animals in Public Settings
- Prevention Measures

Recommendations and Guidelines

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods, they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence, or otherwise or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Preface

The field of infectious diseases is ever changing with emerging pathogens, globalization of people and microbes, escalating antimicrobial resistance, increasing cohorts of children living with immunocompromising conditions, novel diagnostic methods, expanding therapeutic options, and continuous development of vaccines and strategies for implementation. As the conditions on the ground become increasingly complex, so do the roles of infectious diseases experts. On a micro-level, these experts are entrusted to plan the approach to an individual patient with a potentially previously undescribed infection, while on a macro-level they are challenged to expand the field's knowledge, educate others, and steward the public's health.

Our goal is to provide a comprehensive, reliable, up-to-date reference focused on evidence-based, practical information that is required to care for neonates, infants, children, and adolescents with any infectious disease. Our aim is to guide the clinician to understand the problem, diagnose the etiology, and manage the patient to optimize outcome. This scope also includes epidemiology, control, and prevention of infectious diseases that will aid policy development, as well as management of individual patients. Features permeating the fifth edition of this book include web-based resources, important contact information, notation of key references, and electronic links to primary literature for easy access to expanded, current information as well as for obtaining restricted therapeutic agents or accessing experts for management of rare diseases. We have also added new tables, figures, image-illustrated cases, scan- and slide-ready graphics and algorithms, and Key Points boxes consisting of concise summaries.

We have engaged subject-specific experts as authors and have edited all chapters to reflect a prescribed, predictable, and focused format that will reward the reader with answers to the question, What should I do next? With a substantial number of authors from the Centers for Disease Control and Prevention, the American Academy of Pediatrics' Committee on Infectious Diseases and the Section on Infectious Diseases, the Pediatric Infectious Diseases Society, and infection prevention advisory groups, we have attempted to present consistent recommendations and to build a compendium of best practices. Examples of new content are highlighted here, within the context of the four major sections of the book.

Part I. Understanding, Controlling, and Preventing Infectious Diseases: a primer in biostatistics; expanded use of immunoglobulin products; latest vaccines and schedules for routine immunizations and for special hosts, and adverse event–reporting systems; listings of resources in electronic, telephone, and paper media; up-to-date recommendations for infection prevention for hospitals and offices; special considerations for children who are in out-of-home care, are exposed to pets and exotic animals, are traveling, or are immigrating.

Part II. Clinical Syndromes and Cardinal Features of Infectious Diseases: Approach to Diagnosis and Initial Management: new content on conditions that mimic infectious diseases (such as hemophagocytic lymphohistiocytosis and macrophage activation syndrome); developmental stages of innate and adaptive immunity; recognition and management of infections and risks due to congenital and acquired immunocompromising conditions; new chapters on infections related to biologic modifier therapy and to receipt of corticosteroids; expanded content on central nervous system infectious and parainfectious conditions; new morbidities and evidence-based approaches to preventing healthcare-associated infections.

Part III. Etiologic Agents of Infectious Diseases: significant new entries related to molecular diagnostic approach, antimicrobial resistance, and therapies for bacterial infections, especially infections due to staphylococci, pneumococci, gonococci, mycobacteria, and gram-negative bacilli; recently discovered or relevant viruses (including Ebola and Zika), new antiviral therapies, new vaccines, and some under development; evidence and guidance where evidence is incomplete for use and monitoring of agents to treat fungal infections; comprehensive and latest guidance for management of protozoal infections, including toxoplasmosis, malaria, and other pathogens of immigrants.

Part IV. Laboratory Diagnosis and Therapy of Infectious Diseases: through the burgeoning world of molecular diagnostics, the *best tests* for laboratory identification of infectious agents; *differentiating features* of commonly used laboratory tests to measure the inflammatory response and predict the cause; *new insights* into principles of use of anti-infective therapies; *expanded primer* on the pharmacodynamic basis of optimal use of antimicrobial agents; mechanisms and *best laboratory techniques* to detect newly emerging antimicrobial resistance; *new antimicrobial agents* for treating bacterial, fungal, viral, and parasitic infections.

The primary audience for our textbook is the subspecialist in infectious diseases who provides care for or advises on policy regarding infants, children, and adolescents. We hope that our book also serves as a daily "consultant" for pediatricians and family physicians and a valuable resource for surgeons, clinical microbiologists, experts in infection control, health policy makers, and other health professionals who care for and about children.

Sarah S. Long

Marc Fischer

Acknowledgements

With special contributions of clinical images by James H. Brien, DO, Department of Pediatrics, Texas A&M University College of Medicine, Scott & White Memorial Hospital, Temple, Texas.

Dedication

With our spouses (Bob, Laura, and Lisa)

our offspring (Stephen, Suzanne, and Caroline; Meghan and Andrew; Sydney and Madison)

and other loved ones

whose patience and endurance are our bedrock,

We share the achievement of this book.

To our mentors and colleagues, who share

knowledge and stimulate learning,

We give credit for the book's value.

To those who practice medicine as an art based on science,

and for the children whom they will serve,

We offer the book's lessons.

To Larry K. Pickering,

for his advancement of the field of pediatric infectious diseases, *his outstanding leadership of the*

Advisory Committee on Immunization Practices of the Centers
for Disease Control and Prevention,

and for his vital role as an associate editor of Principles and Practice of Pediatric Infectious Diseases

from its inaugural edition through its fourth,

We dedicate this book.

Contributors

Mark J. Abzug MD, Professor of Pediatrics, University of Colorado School of Medicine, Division of Infectious Diseases, Children's Hospital Colorado, Aurora, Colorado

Introduction to Picornaviridae; *Enteroviruses and Parechoviruses*

Elisabeth E. Adderson MD, MSc, Associate Professor of Pediatrics, University of Tennessee Health Sciences Center; Associate Member, Division of Infectious Diseases, St. Jude Children's Research Hospital, Memphis, Tennessee

Infectious Complications of Antibody Deficiency

Allison L. Agwu MD, ScM, Associate Professor of Pediatrics, Johns Hopkins School of Medicine, Baltimore, Maryland

Infectious Complications of HIV Infection

Kevin Alby PhD, D(ABMM), Assistant Professor of Pathology and Laboratory Medicine, University of Pennsylvania School of Medicine, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania

Mechanisms and Detection of Antimicrobial Resistance

Grace M. Aldrovandi MD, CM, Professor of Pediatrics, David Geffen School of Medicine at the University of California Los Angeles; Chief, Division of Infectious Diseases, University of California Los Angeles Medical Center, Los Angeles, California

Immunopathogenesis of HIV-1 Infection

Upton D. Allen MBBS, MSc, FAAP, FRCPC, Hon FRCP(UK), Professor of Paediatrics, University of Toronto, Division of Infectious Diseases, Hospital for Sick Children, Toronto, Ontario, Canada

Adenoviruses

Gerardo Alvarez-Hernández MD, MPH, PhD, Department of Medicine and Health Sciences, Universidad de Sonora, Hermosillo, Sonora, Mexico

Rickettsia rickettsii (Rocky Mountain Spotted Fever)

Krow Ampofo MB, ChB, Professor of Pediatrics, University of Utah Health Sciences Center; Attending Physician, Pediatric Infectious Diseases, Primary Children's Hospital, Salt Lake City, Utah

Streptococcus pneumoniae

Evan J. Anderson MD, Associate Professor of Pediatrics and Medicine, Emory University School of Medicine, Division of Infectious Diseases, Children's Healthcare of Atlanta, Atlanta, Georgia

Campylobacter jejuni and Campylobacter coli; *Other Campylobacter Species*

Margot Anderson MD, Assistant Professor of Pediatrics, Section of Pediatric Infectious Diseases, Tulane University School of Medicine, New Orleans, Louisiana

Filoviruses and Arenaviruses

Stella Antonara PhD, D(ABMM), Clinical Assistant Professor of Pathology, Department of Pathology and Laboratory Medicine, The Ohio State University College of Medicine; Assistant Director, Clinical Microbiology and Immunoserology, Nationwide Children's Hospital, Columbus, Ohio

Citrobacter Species; *Less Commonly Encountered Enterobacteriaceae*; *Proteus, Providencia, and Morganella Species*; *Serratia Species*

Monica I. Ardura DO, MSCS, Associate Professor of Pediatrics, The Ohio State University College of Medicine; Medical Director of Host Defense Program, Pediatrics, Infectious Diseases, and Immunoserlogy, Nationwide Children's Hospital, Columbus, Ohio

Fever and Granulocytopenia; *Infections in Children With Cancer*; *Citrobacter Species*

Paul M. Arguin MD, Chief, Domestic Malaria Unit, Centers for Disease Control and Prevention, Atlanta, Georgia

Plasmodium Species (Malaria)

John C. Arnold MD, Chairman of Pediatrics, Naval Medical Center—San Diego, San Diego, California

Pharyngitis; *Streptococcus pyogenes (Group A Streptococcus)*

Naomi E. Aronson MD, Professor of Medicine, Director, Infectious Diseases Division, Uniformed Services University of the Health Sciences, Bethesda, Maryland

Leishmania Species (Leishmaniasis)

Ann M. Arvin MD, Lucile Salter Packard Professor of Pediatrics, Professor of Microbiology and Immunology, Stanford University School of Medicine, Stanford, California

Varicella-Zoster Virus

Shai Ashkenazi MD, MSc, The Pickel Professor for Pediatric Research, Sackler Faculty of Medicine, Tel Aviv University; Chairman, Department of Pediatrics A, Schneider Children's Medical Center, Petach Tikva, Israel

Plesiomonas shigelloides; *Shigella Species*

Edwin J. Asturias MD, Associate Professor of Pediatrics, University of Colorado School of Medicine; Associate Professor of Epidemiology, Colorado School of Public Health; Associate Director of Center for Global Health, Colorado School of Public Health, Aurora, Colorado

Escherichia coli

David Greenberg MD, Professor of Pediatrics, Faculty of Health Sciences, Gen-Gurion University of the Negev; Chief, Pediatric Infectious Disease Unit, Soroka University Medical Center, Beer-Sheva, Israel

Moraxella Species

Tanya Greywal MD, Department of Dermatology, University of California San Diego; Rady Children's Hospital San Diego, San Diego, California

Dermatophytes and Other Superficial Fungi

Daniel Griffin MD, PhD
Clinical Instructor of Medicine, Division of Infectious Diseases; Associate Research Scientist, Department of Biochemistry and Molecular BioPhysics, Columbia University College of Physicians and Surgeons, New York, New York;
Director, Parasites Without Borders, Inc., Port Washington, New York;
Physician, Infectious Disease and Travel Medicine ProHealth Care, Plainview, New York

Tissue Nematodes

Patricia M. Griffin MD, Chief, Enteric Diseases Epidemiology Branch, Division of Foodborne, Waterborne, and Environmental

Diseases, National Center for Emerging and Zoonotic Infectious Diseases, Centers for Disease Control and Prevention, Atlanta, Georgia

Other Vibrio Species

Alexei A. Grom MD, Professor of Pediatrics, University of Cincinnati College of Medicine; Division of Rheumatology, Cincinnati Children's Hospital Medical Center, Cincinnati, Ohio

Fever and the Inflammatory Response

Kathleen Gutierrez MD, FAAP, Associate Clinical Professor (Emerita), Pediatrics—Infectious Disease, Stanford University School of Medicine, Stanford, California

Osteomyelitis; *Infectious and Inflammatory Arthritis*; *Diskitis*

Julie Gutman MD, MSc, Medical Officer, Malaria Branch, Centers for Disease Control and Prevention, Atlanta, Georgia

Plasmodium Species (Malaria)

Judith A. Guzman-Cottrill DO, Professor of Pediatrics, Division of Infectious Diseases, Oregon Health & Science University, Portland, Oregon

Pediatric Healthcare Epidemiology; *The Systemic Inflammatory Response Syndrome (SIRS), Sepsis, and Septic Shock*

Aron J. Hall DVM, MSPH, Epidemiologist, Division of Viral Diseases, Centers for Disease Control and Prevention, Atlanta, Georgia

Enteric Diseases Transmitted Through Food, Water, and Zoonotic Exposures; *Caliciviruses*

Jin-Young Han MD, PhD, Associate Professor of Pediatrics, University of Arkansas for Medical Sciences; Section of Infectious Diseases, Arkansas Children's Hospital, Little Rock, Arkansas

Aseptic and Viral Meningitis; *Bartonella Species (Cat-Scratch Disease)*

Marvin B. Harper MD, Associate Professor of Pediatrics, Harvard Medical School; Chief Medical Information Officer, Attending Physician in Emergency Medicine and Infectious Diseases, Boston Children's Hospital, Boston, Massachusetts

Pneumonia in the Immunocompromised Host; *Infection Following Bites*

Julie R. Harris PhD, MPH, Epidemiologist, Field Epidemiology Training Program, Centers for Disease Control and Prevention, Atlanta, Georgia

Intestinal Nematodes

Christopher J. Harrison MD, Professor of Pediatrics, University of Missouri-Kansas City School of Medicine; Attending Physician and Director of Infectious Diseases Laboratory, Children's Mercy Hospital Kansas City, Kansas City, Missouri

Chronic Meningitis; *Recurrent Meningitis*; *Focal Suppurative Infections of the Nervous System*

David B. Haslam MD, Associate Professor of Pediatrics, University of Cincinnati College of Medicine; Cincinnati Children's Hospital Medial Center, Cincinnati, Ohio

Classification of Streptococci; *Enterococcus Species*; *Viridans Streptococci, Abiotrophia and Granulicatella Species, and Streptococcus bovis Group*; *Goups C and G Streptococci*; *Other Gram-Positive, Catalase-Negative Cocci: Leuconostoc and Pediococcus Species and Other Genera*

Sarah J. Hawkes MBBS, DTM&H, PhD, Professor of Global Health, Institute for Global Health, University College London, London, United Kingdom

Treponema pallidum (Syphilis)

J. Owen Hendley MD †, Professor of Pediatrics, University of Virginia School of Medicine, Charlottesville, Virginia

Rhinoviruses

Marion C.W. Henry MD, MPH, Commander, Medical Corps, US Navy; Division Head, Pediatric Surgery, Naval Medical Center—San Diego, San Diego, California

Appendicitis

Joseph A. Hilinski MD, Associate Professor of Pediatrics, Emory University School of Medicine, Division of Infectious Diseases, Emory Children's Center, Atlanta, Georgia

Myocarditis; *Pericarditis*

Susan L. Hills MBBS, MTH, Medical Epidemiologist, Arboviral Diseases Branch, Centers for Disease Control and Prevention, Fort Collins, Colorado

Flaviviruses

Scott D. Holmberg MD, MPH, Chief, Epidemiology and Surveillance Branch, Division of Viral Hepatitis, Centers for Disease Control and Prevention, Atlanta, Georgia

Hepatitis C Virus

Deborah Holtzman PhD, Associate Director for Science, Division of Viral Hepatitis, Centers for Disease Control and Prevention, Atlanta, Georgia

Hepatitis C Virus

David K. Hong MD, Medical Director, Karius, Inc., Menlo Park, California

Osteomyelitis; *Infectious and Inflammatory Arthritis*; *Diskitis*

Peter J. Hotez MD, PhD, Dean, National School of Tropical Medicine; Professor of Pediatrics and Molecular Virology and Microbiology, Baylor College of Medicine; Texas Children's Hospital Endowed Chair of Tropical Pediatrics; Head, Section of Pediatric Tropical Medicine; Director, Sabin Vaccine Institute, Texas Children's Hospital Center for Vaccine Development; Professor of Biology, Baylor University; Baker Institute Fellow in Disease and Poverty, Rice University, Houston, Texas

Classification of Parasites; *Intestinal Nematodes*

Katherine K. Hsu MD, MPH, Associate Professor of Pediatrics, Boston University Medical Center; Medical Director, Division of STD Prevention & HIV/AIDS Surveillance, Massachusetts Department of Public Health, Boston, Massachusetts

Neisseria gonorrhoeae; *Other Neisseria Species*

David A. Hunstad MD, Associate Professor of Pediatrics and Molecular Microbiology, Washington University School of Medicine & Health Sciences; Attending Physician and Chief, Pediatric Infectious Diseases, St. Louis Children's Hospital, St. Louis, Missouri

Infectious Complications in Special Hosts

Loris Y. Hwang MD, MS, Associate Professor of Pediatrics, Director of Adolescent Reproductive Health in Clinical Care and Research, David Geffen School of Medicine at The University of California Los Angeles; Attending Physician, Division of Adolescent and Young Adult Medicine, University of California Los Angeles, Mattel Children's Hospital UCLA, Los Angeles, California

Human Papillomaviruses

Mary Anne Jackson MD, Professor of Pediatrics, University of Missouri-Kansas City School of Medicine; Director, Division of Infectious Diseases, Children's Mercy Hospital Kansas City; Kansas City, Missouri

Lymphatic System and Generalized Lymphadenopathy;

Mediastinal and Hilar Lymphadenopathy

Richard F. Jacobs MD, Professor of Pediatrics, Robert H. Fiser, Jr., M.D. Endowed Chair in Pediatrics, University of Arkansas for Medical Sciences, Little Rock, Arkansas

Bartonella Species (Cat-Scratch Disease)

Ravi Jhaveri MD, Associate Professor of Pediatrics, University of North Carolina School of Medicine; Division of Infectious Diseases, University of North Carolina Medical Center, Chapel Hill, North Carolina

Fever Without Localizing Signs

Kateřina Jirků-Pomajbíková DVM, PhD, Institute of Parasitology, Biology Center of the Czech Academy of Sciences, České Budějovice, Czech Republic

Balantioides coli (Formerly Balantidium coli)

Jeffrey L. Jones MD, MPH, Medical Epidemiologist, Division of Parasitic Diseases and Malaria, Center for Global Health, Centers for Disease Control and Prevention, Atlanta, Georgia

Clonorchis, Opisthorchis, Fasciola, and Paragonimus Species

Mahima Karki, Research Assistant, Department of Pediatric Surgery, Boston Children's Hospital, Boston, Massachusetts

Peritonitis

M. Gary Karlowicz MD, Professor of Pediatrics, Eastern Virginia Medical School; Attending Physician, Division of Neonatal-Perinatal Medicine, Children's Hospital of The King's Daughters, Norfolk, Virginia

Healthcare-Associated Infections in the Neonate

Ben Z. Katz MD, Professor of Pediatrics, Northwestern University Feinberg School of Medicine; Attending Physician, Division of Infectious Diseases, Ann & Robert H. Lurie Children's Hospital of Chicago, Chicago, Illinois

Epstein-Barr Virus (Mononucleosis and Lymphoproliferative Disorders)

Ishminder Kaur MD, Clinical Assistant Professor of Pediatrics, Drexel University College of Medicine, Section of Infectious Diseases, St. Christopher's Hospital for Children, Philadelphia, Pennsylvania

Mucocutaneous Symptom Complexes; *Abdominal Symptom Complexes*; *Topical Antimicrobial Agents*

Gilbert J. Kersh PhD, Research Biologist, Division of Vector-Borne Diseases, Centers for Disease Control and Prevention, Atlanta, Georgia

Coxiella burnetii (Q Fever)

Jay S. Keystone MD, MSc (CTM), Professor of Medicine, University of Toronto, Tropical Disease Unit, Toronto General Hospital, Toronto, Ontario, Canada

Protection of Travelers

Muhammad Ali Khan MD, MPH, Assistant Professor of Pediatrics, George Washington University School of Medicine & Health Sciences; Director of Endoscopy, Pediatric Gastroenterology and Hepatology, Children's National Health System, Washington, District of Columbia

Chronic Hepatitis

David W. Kimberlin MD, Professor of Pediatrics, University of Alabama at Birmingham School of Medicine; Sergio Stagno Endowed Chair in Pediatric Infectious Diseases, Children's Hospital of Alabama, Birmingham, Alabama

Introduction to Herpesviridae; *Herpes Simplex Virus*; *Antiviral Agents*

Martin B. Kleiman MD, Ryan White Professor Emeritus of Pediatrics, Indiana University School of Medicine, Ryan White Center for Pediatric Infectious Disease and Global Health, Riley Hospital for Children, Indianapolis, Indiana

Histoplasma capsulatum (Histoplasmosis)

Bruce S. Klein MD, Professor of Pediatrics and Medicine, Medical Microbiology, and Immunology, Division of Infectious Diseases, School of Medicine and Public Health, University of Wisconsin Madison, Madison, Wisconsin

Blastomyces dermatitidis (Blastomycosis)

Karl Klontz MD, MPH, Medical Epidemiologist, Center for Food Safety and Applied Nutrition, United States Food and Drug Administration, College Park, Maryland

Clostridium difficile

Barbara Knust DVM, MPH, Epidemiologist, Viral Special Pathogens Branch, Centers for Disease Control and Prevention, Atlanta, Georgia

Bunyaviruses

Andrew Y. Koh MD, Assistant Professor of Pediatrics and Microbiology, Director of Pediatric Hematopoietic Stem Cell Transplantation, University of Texas Southwestern Medical Center, Dallas, Texas

Fever and Granulocytopenia; *Infections in Children With Cancer*

E. Kent Korgenski MS, MT(ASCP), Outcomes Data Analyst/Consultant, Intermountain Healthcare, Pediatric Clinical Program, University of Utah Department of Pediatrics, Salt Lake City, Utah

Laboratory Diagnosis of Infection Due to Bacteria, Fungi, Parasites, and Rickettsiae

Paul Krogstad MD, Professor of Pediatrics and Molecular and Medical Pharmacology, David Geffen School of Medicine at The University of California Los Angeles, Los Angeles, California

Diagnosis and Clinical Manifestations of HIV Infection

Preeta Krishnan Kutty MD, MPH, Medical Epidemiologist, National Center for Immunizations and Respiratory Diseases, Centers for Disease Control and Prevention, Atlanta, Georgia

Chlamydia (Chlamydophila) psittaci (Psittacosis)

Christine T. Lauren MD, Assistant Professor of Dermatology and Pediatrics, Columbia University Medical Center, New York, New York

Papules, Nodules, and Ulcers

Hillary S. Lawrence MD, Assistant Professor of Dermatology, University of Oklahoma Health Sciences Center, Oklahoma City, Oklahoma

Superficial Bacterial Skin Infections and Cellulitis

Amy Leber PhD, Clinical Associate Professor of Pathology and Pediatrics, The Ohio State University College of Medicine; Director of Clinical Microbiology and Immunoserology, Department of Laboratory Medicine, Nationwide Children's Hospital, Columbus, Ohio

Klebsiella and Raoultella Species; *Enterobacter, Cronobacter, and Pantoea Species*; *Acinetobacter Species*; *Less Commonly Encountered Nonenteric Gram-Negative Bacilli*; *Eikenella, Pasteurella, and Chromobacterium Species*

Grace M. Lee MD, MPH, Associate Professor of Population Medicine & Pediatrics, Harvard Medical School; Director, Center for Healthcare Research in Pediatrics, Harvard Pilgrim Health Care Institute & Harvard Medical School; Associate Medical Director of Infection Control, Boston Children's Hospital, Boston,

Massachusetts

Pneumonia in the Immunocompromised Host

Eugene Leibovitz MD, Professor of Pediatrics, Faculty of Health Sciences, Ben-Gurion University of the Negev; Chief, Pediatric Emergency Medicine Department, Attending Physician, Pediatric Infectious Disease Unit, Soroka University Medical Center, Beer-Sheva, Israel

Moraxella Species

Eyal Leshem MD, Division of Viral Diseases, National Center for Immunization and Respiratory Diseases, Centers for Disease Control and Prevention, Atlanta, Georgia

Viral Gastroenteritis

Stéphanie Levasseur MD, FRCPC, Assistant Professor of Pediatrics, Columbia University Medical Center; Division of Cardiology, Morgan Stanley Children's Hospital of New York-Presbyterian, New York, New York

Endocarditis and Other Intravascular Infections

David B. Lewis MD, Professor of Pediatrics, Chief, Division of Allergy, Immunology, and Rheumatology, Department of Pediatrics, Stanford University School of Medicine, Stanford, California

Hemophagocytic Lymphohistiocytosis and Macrophage Activation Syndrome; *Infectious Complications of Cell-Mediated Immunity Other Than AIDS: Primary Immunodeficiencies*

Robyn A. Livingston MD, Associate Professor, University of Missouri-Kansas City School of Medicine; Medical Director, Infection Prevention and Control, Attending Physician, Pediatric Infectious Diseases, Children's Mercy Hospital Kansas City, Kansas City, Missouri

Recurrent Meningitis

Eloisa Llata MD, MPH, Medical Epidemiologist, Division of Sexually Transmitted Disease Prevention, Centers for Disease Control and Prevention, Atlanta, Georgia

Pelvic Inflammatory Disease

Sarah S. Long MD, Professor of Pediatrics, Drexel University College of Medicine; Chief, Section of Infectious Diseases, St. Christopher's Hospital for Children, Philadelphia, Pennsylvania

Mucocutaneous Symptom Complexes; *Prolonged, Recurrent, and Periodic Fever Syndromes*; *Respiratory Tract Symptom Complexes*; *Bordetella pertussis (Pertussis) and Other Bordetella Species*; *Anaerobic Bacteria: Classification, Normal Flora, and Clinical Concepts*; *Clostridium botulinum (Botulism)*; *Laboratory Manifestations of Infectious Diseases*; *Principles of Anti-Infective Therapy*

Ben A. Lopman PhD, MPH, Epidemiologist, Division of Viral Diseases, National Center for Immunization and Respiratory Diseases, Centers for Disease Control and Prevention, Atlanta, Georgia

Viral Gastroenteritis

Yalda C. Lucero MD, PhD, Assistant Professor of Pediatrics, Faculty of Medicine, Hospital Luis Calvo Mackenna, University of Chile, Santiago, Chile

Aeromonas Species

Jorge Luján-Zilbermann MD, MS, Clinical Associate Professor of Pediatrics, University of South Florida College of Medicine; Medical Director, Hill-Top Research, Inc., St. Petersburg, Florida

Infections in Hematopoietic Stem Cell Transplant Recipients

Katherine Luzuriaga MD, Professor of Program in Molecular

Medicine, Pediatrics, and Medicine, Vice Provost, UMass Center for Clinical and Translational Science and Global Health, University of Massachusetts Medical School, Worcester, Massachusetts

Introduction to Retroviridae; *Human T-Cell Lymphotropic Viruses*; *Human Immunodeficiency Virus*

Noni E. MacDonald MD, MSc, FRCPC, Professor of Pediatric Infectious Diseases, Department of Pediatrics, Dalhousie University; Co-Director MicroResearch, IWK Health Center, Halifax, Nova Scotia, Canada

Epididymitis, Orchitis, and Prostatitis

Yvonne A. Maldonado MD, Senior Associate Dean for Faculty Development and Diversity, Professor of Pediatrics and Health Research and Policy, Stanford University School of Medicine; Chief, Division of Pediatric Infectious Diseases, Berger-Raynolds Distinguished Fellow and Attending Physician, Lucile Packard Children's Hospital at Stanford, Stanford, California

Rubella Virus; *Mumps Virus*; *Rubeola Virus: Measles and Subacute Sclerosing Panencephalitis*; *Polioviruses*

John Manaloor MD, Assistant Professor of Clinical Pediatrics, Indiana University School of Medicine; Ryan White Center for Pediatric Infectious Disease, Riley Hospital for Children at Indiana University Health, Indianapolis, Indiana

Agents of Eumycotic Mycetoma: Pseudallescheria boydii (Anamorph Scedosporium apiospermum)

Chitra S. Mani MBBS, DCH, FAAP, Professor of Pediatrics, Medical College of Georgia; Attending Physician, Division of Infectious Diseases, Children's Medical Center, Augusta, Georgia

Acute Pneumonia and Its Complications

Kalpana Manthiram MD, MSCI, Adjunct Assistant Professor, Division of Pediatric Infectious Diseases, Vanderbilt University School of Medicine, Nashville, Tennessee; Clinical Fellow, National

Human Genome Research Institute, National Institutes of Health, Bethesda, Maryland

Prolonged, Recurrent, and Periodic Fever Syndromes

Gary S. Marshall MD, Professor of Pediatrics, University of Louisville School of Medicine; Chief, Division of Infectious Diseases, Kosair Children's Hospital, Louisville, Kentucky

Chronic Fatigue Syndrome

Stacey W. Martin MSc, Epidemiologist, Division of Bacterial Diseases, Centers for Disease Control and Prevention, Atlanta, Georgia

Principles of Epidemiology and Public Health

Almea Matanock MD, Preventive Medicine Resident, Population Health Workforce Branch, Division of Scientific Education and Professional Development, Centers for Disease Control and Prevention, Atlanta, Georgia

Vibrio cholerae (Cholera)

Catalina Matiz MD, Assistant Professor of Dermatology, University of California San Diego School of Medicine; Department of Dermatology, Rady Children's Hospital San Diego, San Diego, California

Subcutaneous Tissue Infections and Abscesses

Alison C. Mawle PhD, Senior Scientist, National Center for Immunization and Respiratory Diseases, Centers for Disease Control and Prevention, Atlanta, Georgia

Active Immunization

Tony Mazzulli MD, Professor of Laboratory Medicine and Pathobiology, University of Toronto; Deputy Chief Microbiologist-in-Chief, Mount Sinai Hospital, Toronto, Ontario, Canada

Laboratory Diagnosis of Infection Due to Viruses, Chlamydia, Chlamydophila, and Mycoplasma

Kathleen A. McGann MD, Vice Chair of Pediatrics for Education, Dr. Glen and Muriel Kiser Professor of Pediatrics, Duke University Medical Center; Attending Physician, Infectious Diseases, Duke Children's Hospital, Durham, North Carolina

Respiratory Tract Symptom Complexes

Kenneth McIntosh MD, Professor of Pediatrics, Harvard Medical School, Children's Hospital Boston, Boston, Massachusetts

Pneumonia in the Immunocompromised Host

Lucy A. McNamara PhD, MS, Epidemiologist, Meningitis and Vaccine Preventable Diseases Branch, National Center for Immunization and Respiratory Diseases, Centers for Disease Control and Prevention, Atlanta, Georgia

Principles of Epidemiology and Public Health

Michal Meir MD, Attending Physician, Pediatric Infectious Diseases, Ruth Rappaport Children's Hospital, Rambam Health Care Campus, Haifa, Israel

Immunologic Development and Susceptibility to Infection

Debrah Meislich MD, Assistant Professor of Pediatrics, Cooper Medical School of Rowan University; Division of Infectious Diseases, Children's Regional Hospital-Cooper, Camden, New Jersey

Anaerobic Cocci; *Anaerobic Gram-Positive Nonsporulating Bacilli (Including Actinomyces)*

H. Cody Meissner MD, Professor of Pediatrics, Tufts University School of Medicine; Director, Division of Pediatric Infectious Disease, Tufts Medical Center, Boston, Massachusetts

Passive Immunization; *Bronchiolitis*; *Respiratory Syncytial Virus*

Elissa Meites MD, MPH, Medical Officer, Division of Viral

Diseases, Centers for Disease Control and Prevention, Atlanta, Georgia

Trichomonas vaginalis

Asunción Mejías MD, PhD, MSCS, Associate Professor of Pediatrics, Division of Infectious Diseases, The Ohio State University College of Medicine; Principal Investigator, Center for Vaccines and Immunity, The Research Institute at Nationwide Children's Hospital, Columbus, Ohio

Serratia Species; *Parainfluenza Viruses*

Jussi Mertsola MD, Professor of Pediatrics, Turku University Hospital, Turku, Finland

Bordetella pertussis (Pertussis) and Other Bordetella Species

Kevin Messacar MD, Assistant Professor of Pediatrics, University of Colorado School of Medicine; Division of Infectious Diseases, Children's Hospital Colorado, Aurora, Colorado

Introduction to Picornaviridae; *Enteroviruses and Parechoviruses*

Mohammed Nael Mhaissen MD, Pediatric Infectious Disease Specialist, Valley Children's Hospital, Madera, California

Cryptosporidium Species; *Cystoisospora (Isospora) and Cyclospora Species*; *Microsporidia*

Marian G. Michaels MD, MPH, Professor of Pediatrics and Surgery, University of Pittsburgh School of Medicine; Division of Pediatric Infectious Diseases, Children's Hospital of Pittsburgh of UPMC, Pittsburgh, Pennsylvania

Eosinophilic Meningitis; *Infections in Solid Organ Transplant Recipients*

Melissa B. Miller PhD, D(ABMM), Professor of Pathology and Laboratory Medicine, University of North Carolina School of

Medicine; Director, Clinical Molecular Microbiology Laboratory; Associate Director, Clinical Microbiology-Immunology Laboratory, University of North Carolina Hospitals, Chapel Hill, North Carolina

Mechanisms and Detection of Antimicrobial Resistance

Eric D. Mintz MD, MPH, Team Lead, Global Epidemiology, Waterborne Diseases Prevention Branch, Division of Foodborne, Waterborne, and Environmental Diseases, Centers for Disease Control and Prevention, Atlanta, Georgia

Vibrio cholerae (Cholera)

John F. Modlin MD, Deputy Director, Polio, Bill and Melinda Gates Foundation; Professor Emeritus of Pediatrics and Medicine, Geisel School of Medicine at Dartmouth, Seattle, Washington

Introduction to Picornaviridae; Enteroviruses and Parechoviruses

Parvathi Mohan MD, MBBS, Professor of Pediatrics, George Washington University School of Medicine & Health Sciences; Interim Chief and Director of Hepatology, Pediatric Gastroenterology, and Hepatology, Children's National Health System, Washington, District of Columbia

Chronic Hepatitis

Susan P. Montgomery DVM, MPH, Epidemiology Team Lead, Parasitic Diseases Branch, Centers for Disease Control and Prevention, Atlanta, Georgia

Diphyllobothrium, Dipylidium, and Hymenolepis Species; Blood Trematodes: Schistosomiasis

José G. Montoya MD, FACP, FIDSA

Professor of Medicine, Division of Infectious Diseases and Geographic Medicine, Stanford University School of Medicine, Stanford, California;

Director, Palo Alto Medical Foundation Toxoplasma Serology Laboratory, National Reference Center for the Study and Diagnosis of Toxoplasmosis, Palo Alto, California

Toxoplasma gondii (Toxoplasmosis)

Pedro L. Moro MD, MPH, Epidemiologist, Immunization Safety Office, Division of Healthcare Quality Promotion, National Center for Zoonotic and Emerging Infectious Diseases, Centers for Disease Control and Prevention, Atlanta, Georgia

Echinococcus Species: Agents of Echinococcosis

Anna-Barbara Moscicki MD, Professor of Pediatrics, David Geffen School of Medicine at The University of California Los Angeles; Chief, Adolescent and Young Adult Medicine, Department of Pediatrics, The University of California Los Angeles, Mattel Children's Hospital UCLA, Los Angeles, California

Human Papillomaviruses

R. Lawrence Moss MD, E. Thomas Boles, Jr. Professor of Surgery, The Ohio State University College of Medicine; Surgeon-in-Chief, Nationwide Children's Hospital, Columbus, Ohio

Peritonitis; *Appendicitis*; *Intra-Abdominal, Visceral, and Retroperitoneal Abscesses*

Angela L. Myers MD, MPH, Associate Professor of Pediatrics, University of Missouri-Kansas City School of Medicine; Division of Infectious Diseases, Pediatric Infectious Diseases Fellowship Program Director, Children's Mercy Hospital Kansas City, Kansas City, Missouri

Abdominal and Retroperitoneal Lymphadenopathy; *Localized Lymphadenitis, Lymphadenopathy, and Lymphangitis*

Simon Nadel MRCP, MRCPCH, FRCP, Consultant and Adjunct Professor in Paediatric Intensive Care, St. Mary's Hospital and Imperial College, London, United Kingdom

Acute Bacterial Meningitis Beyond the Neonatal Period

Michael N. Neely MD, MSc, FCP, Associate Professor and Clinical Scholar, Division of Infectious Diseases, Department of Pediatrics, Keck School of Medicine, University of Southern California; Director, Laboratory of Applied Pharmacokinetics and Bioinformatics, The Saban Research Institute, Children's Hospital Los Angeles, Los Angeles, California

Pharmacokinetic-Pharmacodynamic Basis of Optimal Antibiotic Therapy

Karen P. Neil MD, MSPH, Epidemic Intelligence Service Officer, Division of Foodborne, Waterborne, and Environmental Diseases, Centers for Disease Control and Prevention, Atlanta, Georgia

Enteric Diseases Transmitted Through Food, Water, and Zoonotic Exposures

Joanna Nelson MD, Clinical Assistant Professor, Stanford University School of Medicine, Division of Infectious Disease, Stanford University Medical Center, Stanford, California

Entamoeba histolytica (Amebiasis); *Other Entamoeba, Amebas, and Intestinal Flagellates*; *Naegleria fowleri*; *Acanthamoeba Species*

Noele P. Nelson MD, PhD, MPH, Medical Epidemiologist, Division of Viral Hepatitis, Centers for Disease Control and Prevention, Atlanta, Georgia

Hepatitis A Virus

William L. Nicholson MS, PhD, Research Microbiologist and Chief, Pathogen Biology and Ecology Activity, Rickettsial Zoonoses Branch, Centers for Disease Control and Prevention, Atlanta, Georgia

Family Anaplasmataceae (Anaplasmosis, Ehrlichiosis, Neorickettsiosis, and Neoehrlichiosis)

Victor Nizet MD, Professor of Pediatrics and Pharmacy, University of California San Diego, La Jolla, California

Pharyngitis; *Streptococcus pyogenes (Group A Streptococcus)*

Amy Jo Nopper MD, Professor of Pediatrics, University of Missouri-Kansas City School of Medicine; Director, Division of Pediatric Dermatology, Children's Mercy Hospital Kansas City, Kansas City, Missouri

Superficial Bacterial Skin Infections and Cellulitis

Theresa J. Ochoa MD
Associate Professor of Pediatrics, Tropical Medicine Institute, Universidad Peruana Cayetano Heredia, Lima, Peru;
Associate Professor of Epidemiology, School of Public Health, University of Texas Health Science Center at Houston, Houston, Texas

Yersinia Species

Walter A. Orenstein MD, DSc (Hon), Professor of Medicine, Pediatrics, Global Health and Epidemiology, Department of Medicine, Division of Infectious Diseases, Emory University School of Medicine, Atlanta, Georgia

Active Immunization

Miguel O'Ryan MD, Professor and Faculty of Medicine of Microbiology and Mycology Program, Institute of Biomedical Sciences, University of Chile, Santiago, Chile

Yersinia Species; *Aeromonas Species*

Christopher D. Paddock MD, MPHTM, Medical Officer, Rickettsial Zoonoses Branch, Centers for Disease Control and Prevention, Atlanta, Georgia

Rickettsia rickettsii (Rocky Mountain Spotted Fever)

Harpreet Pall MD, Associate Professor of Pediatrics, Drexel University College of Medicine; Chief, Section of Gastroenterology, St. Christopher's Hospital for Children, Philadelphia, Pennsylvania

Inflammatory Enteritis

Suresh Kumar Panuganti DCH, DNB (Pediatrics), Fellowship in Pediatric Critical Care, St. Mary's Hospital & Children's Acute Transport Services, London, United Kingdom

Acute Bacterial Meningitis Beyond the Neonatal Period

Diane E. Pappas MD, JD, Professor of Pediatrics, University of Virginia School of Medicine; University of Virginia Health System, Charlottesville, Virginia

The Common Cold; *Rhinoviruses*

Robert F. Pass MD, Beth Gordy Dubina Professor of Pediatrics, University of Alabama at Birmingham School of Medicine; Director, Pediatric Hospital Medicine, Children's Hospital of Alabama, Birmingham, Alabama

Viral Infections in the Fetus and Neonate; *Cytomegalovirus*

Thomas F. Patterson MD, Professor of Medicine, Chief, Division of Infectious Diseases; Director, San Antonio Center for Medical Mycology, The University of Texas Health Science Center at San Antonio, San Antonio, Texas

Classification of Fungi; *Agents of Hyalohyphomycosis and Phaeohyphomycosis*; *Agents of Mucormycosis*; *Malassezia Species*; *Sporothrix schenckii Complex (Sporotrichosis)*; *Cryptococcus Species*

Monica E. Patton MD, Division of Sexually Transmitted Disease Prevention, Centers for Disease Control and Prevention, Atlanta, Georgia

Skin and Mucous Membrane Infections and Inguinal Lymphadenopathy

Stephen I. Pelton MD, Professor of Pediatrics and Epidemiology, Boston University Schools of Medicine and Public Health; Chief, Section of Pediatric Infectious Diseases, Boston Medical Center, Boston, Massachusetts

Otitis Media

Brett W. Petersen MD, MPH, Medical Officer, National Center for Emerging and Zoonotic Infectious Diseases, Centers for Disease Control and Prevention, Atlanta, Georgia

Poxviridae

Larry K. Pickering MD, Adjunct Professor of Pediatrics, Department of Pediatrics, Emory University School of Medicine, Atlanta, Georgia

Active Immunization

Swetha Pinninti MD, Assistant Professor of Pediatrics, University of Nebraska Medical Center, Omaha, Nebraska

Viral Infections in the Fetus and Neonate

Paul J. Planet MD, Assistant Professor of Pediatrics, The Perelman School of Medicine at the University of Pennsylvania; Attending Physician, Division of Infectious Diseases, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

Pseudomonas aeruginosa

Andrew J. Pollard BSc, MBBS, MRCP(UK), MA, DIC, PhD, FRCPCH, FMedSci, Professor of Paediatric Infection and Immunity, Department of Paediatrics, University of Oxford; Honorary Consultant Paediatrician, Children's Hospital, Oxford, United Kingdom

Neisseria meningitidis

Klara M. Posfay-Barbe MD, MS, Head of Pediatric Infectious Diseases, Children's Hospital of Geneva, University Hospitals of Geneva, Geneva, Switzerland

Eosinophilic Meningitis

Casper S. Poulsen MSc, Doctoral Student, Research Group for Genomic Epidemiology, Technical University of Denmark, Lyngby, Denmark

Endolimax nana

Susan M. Poutanen MD, MPH, FRCPC, Associate Professor of Laboratory Medicine and Pathobiology & Medicine, University of Toronto; Microbiologist & Infectious Disease Physician, University Health Network & Mount Sinai Hospital, Toronto, Ontario, Canada

Human Coronaviruses

Ann M. Powers PhD, Chief, Virology Activity, Arboviral Diseases Branch, Division of Vector-Borne Diseases, Centers for Disease Control and Prevention, Fort Collins, Colorado

Togaviridae: Alphaviruses

Charles G. Prober MD, Professor of Pediatrics, Microbiology, and Immunology, Senior Associate Dean for Medical Education, Stanford University School of Medicine, Stanford, California

Introduction to Herpesviridae; *Herpes Simplex Virus*

Octavio Ramilo MD, Henry G. Cramblett Chair in Infectious Diseases, Professor of Pediatrics, The Ohio State University College of Medicine; Chief, Division of Infectious Diseases, Nationwide Children's Hospital; Principal Investigator, Center for Vaccines and Immunity, The Research Institute at Nationwide Children's Hospital, Columbus, Ohio

Parainfluenza Viruses

Shawn J. Rangel MD, Associate Professor of Surgery, Harvard Medical School; Department of Pediatric Surgery, Boston Children's Hospital, Boston, Massachusetts

Peritonitis

Suchitra Rao MBBS, Assistant Professor of Pediatrics (Infectious Diseases, Hospital Medicine, and Epidemiology), University of Colorado School of Medicine; Sections of Infectious Diseases and

Hospital Medicine, Children's Hospital Colorado, Aurora, Colorado

BK, JC, and Other Human Polyomaviruses

Sarah A. Rawstron MBBS, Clinical Associate Professor of Pediatrics, Icahn School of Medicine at Mount Sinai; Pediatric Residency Program Director, The Brooklyn Hospital Center, Brooklyn, New York

Treponema pallidum (Syphilis); *Other Treponema Species*

Jennifer S. Read MD, MS, MPH, DTM&H, Associate Director for Clinical Research/Division of Allergy, Immunology, and Transplantation, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, Maryland

Epidemiology and Prevention of HIV Infection in Children and Adolescents

Michael D. Reed PharmD, FCCP, FCP, Professor of Pediatrics, Case Western Reserve University School of Medicine; Director, Rainbow Clinical Research Center, Rainbow Babies and Children's Hospital, University Hospitals Cleveland Medical Center, Cleveland, Ohio

Pharmacokinetic-Pharmacodynamic Basis of Optimal Antibiotic Therapy

Ryan F. Relich PhD, D(ABMM), MLS(ASCP)CMSMCM, Assistant Professor of Clinical Pathology and Laboratory Medicine, Indiana University School of Medicine; Associate Medical Director, Division of Clinical Microbiology, Indiana University Health Pathology Laboratory, Indianapolis, Indiana

Laboratory Diagnosis of Infection Due to Bacteria, Fungi, Parasites, and Rickettsiae

Megan E. Reller MD, PhD, MPH, DTM&H, Instructor, Duke University School of Medicine, Division of Infectious Diseases, Duke Children's Hospital, Durham, North Carolina

Salmonella Species

Neil Rellosa MD, Assistant Professor of Pediatrics, Drexel University College of Medicine; Attending Physician, Sections of Infectious Diseases and Immunology, St. Christopher's Hospital for Children, Philadelphia, Pennsylvania

Fusobacterium Species

Katherine A. Rempe PhD, Molecular Microbiology Fellow, Actelion Clinical Research, Cherry Hill, New Jersey

Classification of Bacteria; *Haemophilus influenzae*

Melissa A. Reyes MD, MPH, Staff Dermatologist, Palo Alto Medical Foundation, Dublin, California

Purpura

Samuel E. Rice-Townsend MD, Assistant Professor of Surgery, Harvard Medical School, Department of Pediatric Surgery, Boston Children's Hospital, Boston, Massachusetts

Peritonitis

Frank O. Richards Jr., MD, Director, River Blindness Elimination Program, Lymphatic Filariasis Elimination Program, and Schistosomiasis Control Program, The Carter Center, Atlanta, Georgia

Diphyllobothrium, Dipylidium, and Hymenolepis Species; *Blood Trematodes: Schistosomiasis*

José R. Romero MD, FAAP, FIDSA, FPIDS, Professor of Pediatrics, University of Arkansas for Medical Sciences; Horace C. Cabe Endowed Chair in Infectious Diseases, Director, Pediatric Infectious Diseases Section, Arkansas Children's Hospital, Little Rock, Arkansas

Aseptic and Viral Meningitis

David A. Rosen MD, PhD, Instructor in Pediatrics, Washington University School of Medicine & Health Sciences; Division of Pediatric Infectious Diseases, St. Louis Children's Hospital, St. Louis, Missouri

Infectious Complications in Special Hosts

Christina A. Rostad MD, Instructor in Pediatrics, Emory University School of Medicine; Division of Infectious Diseases, Emory Children's Center, Atlanta, Georgia

Myocarditis; *Pericarditis*

G. Ingrid J.G. Rours MD, PhD, Department of Medical Microbiology and Infectious Diseases, Department of Paediatrics, Erasmus Medical Center, Rotterdam, Netherlands

Chlamydia trachomatis

Janell A. Routh MD, MHS, Medical Officer, Viral Vaccine Preventable Diseases Branch, Division of Viral Diseases, Centers for Disease Control and Prevention, Atlanta, Georgia

Vibrio cholerae (Cholera)

Anne H. Rowley MD, Professor of Pediatrics and Microbiology/Immunology, Northwestern University Feinberg School of Medicine; Attending Physician, Division of Infectious Diseases, The Ann & Robert H. Lurie Children's Hospital of Chicago, Chicago, Illinois

Kawasaki Disease

Lorry G. Rubin MD

Professor of Pediatrics, Hofstra Northwell School of Medicine, Hempstead, New York;
Director of Pediatric Infectious Diseases, Steven and Alexandra Cohen Children's Medical Center of New York, New Hyde Park, New York

Capnocytophaga Species; *Francisella tularensis (Tularemia)*; *Legionella Species*; *Streptobacillus* *moniliformis (Rat-Bite Fever); Other Gram-Negative Coccobacilli*

Edward T. Ryan MD, Professor of Medicine, Harvard Medical School; Professor of Immunology & Infectious Diseases, Harvard School of Public Health; Director, Global Infectious Diseases, Division of Infectious Diseases, Massachusetts General Hospital, Boston, Massachusetts

Antiparasitic Agents

Lisa Saiman MD, MPH, Professor of Pediatrics, Columbia University Medical Center, Division of Infectious Diseases, Morgan Stanley Children's Hospital of New York-Presbyterian, New York, New York

Endocarditis and Other Intravascular Infections

Julia S. Sammons MD, Assistant Professor of Clinical Pediatrics, University of Pennsylvania School of Medicine; Division of Infectious Diseases, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

Clinical Syndromes of Device-Associated Infections

Laura Sass MD, Assistant Professor of Pediatrics, Eastern Virginia Medical School; Attending Physician, Division of Pediatric Infectious Diseases, Children's Hospital of The King's Daughters, Norfolk, Virginia

Healthcare-Associated Infections in the Neonate

Jason B. Sauberan PharmD, Clinical Research Pharmacist, Neonatal Research Institute, Sharp Mary Birch Hospital for Women and Newborns, San Diego, California

Antimicrobial Agents

Sarah Schillie MD, MPH, MBA, Medical Epidemiologist, Division of Viral Hepatitis, Centers for Disease Control and Prevention, Atlanta, Georgia

Hepatitis B and Hepatitis D Viruses

Grant S. Schulert MD, PhD, Instructor, University of Cincinnati College of Medicine; Division of Rheumatology, Cincinnati Children's Hospital Medical Center, Cincinnati, Ohio

Fever and the Inflammatory Response

Jennifer E. Schuster MD, MSCI, Assistant Professor of Pediatrics, University of Missouri-Kansas City School of Medicine; Division of Infectious Diseases, Children's Mercy Hospital Kansas City, Kansas City, Missouri

Human Metapneumovirus

Kevin L. Schwartz MD, MSc, Public Health Ontario, Toronto, Ontaraio, Canada

Protection of Travelers

Bethany K. Sederdahl BS, Research Coordinator, Emory University School of Medicine; Division of Pediatric Infectious Diseases, Children's Healthcare of Atlanta, Atlanta, Georgia

Other Campylobacter Species

Jose A. Serpa MD, MS, Assistant Professor of Medicine, Baylor College of Medicine; Director of Infectious Diseases Fellowship Training Program, Texas Children's Hospital, Houston, Texas

Taenia solium, Taenia asiatica, and Taenia saginata: Taeniasis and Cysticercosis; Taenia Multiceps (multiceps) and Taenia serialis: Coenurosis

Kara N. Shah MD, PhD, Associate Professor of Pediatrics and Dermatology, University of Cincinnati College of Medicine; Medical Director, Division of Dermatology, Cincinnati Children's Hospital, Cincinnati, Ohio

Urticaria and Erythema Multiforme

Samir S. Shah MD, Professor of Pediatrics, University of

Cincinnati College of Medicine; Attending Physician, Divisions of Infectious Diseases and Hospital Medicine; James M. Ewell Endowed Chair, Director, Division of Hospital Medicine, Cincinnati Children's Hospital Medical Center, Cincinnati, Ohio

Chlamydophila (Chlamydia) pneumoniae; *Mycoplasma pneumoniae*; *Other Mycoplasma Species*; *Ureaplasma urealyticum*

Andi L. Shane MD, MPH, MSc, Associate Professor of Pediatrics, The Marcus Professor of Hospital Epidemiology and Infection Prevention, Emory University School of Medicine; Division of Infectious Diseases, Children's Healthcare of Atlanta, Atlanta, Georgia

Infections Associated With Group Childcare; *Approach to the Diagnosis and Management of Gastrointestinal Tract Infections*

Eugene D. Shapiro MD, Professor of Pediatrics, Epidemiology, and Investigative Medicine, Yale University Schools of Medicine, Public Health, and Graduate School of Arts and Sciences; Attending Pediatrician, The Children's Hospital at Yale-New Haven, New Haven, Connecticut

Fever Without Localizing Signs; *Leptospira Species (Leptospirosis)*; *Borrelia burgdorferi (Lyme Disease)*; *Other Borrelia Species and Spirillum minus*

Jana Shaw MD, MPH, Associate Professor of Pediatrics, State University of New York; Division of Infectious Diseases, Golisano Children's Hospital, Syracuse, New York

Infections of the Oral Cavity

Avinash K. Shetty MD, Associate Dean for Global Health, Professor of Pediatrics, Wake Forest School of Medicine; Chief, Division of Pediatric Infectious Diseases, Brenner Children's Hospital, Winston-Salem, North Carolina

Rubella Virus; Mumps Virus; Rubeola Virus: Measles and Subacute Sclerosing Panencephalitis

Linda M. Dairiki Shortliffe, MD, Stanley McCormick Memorial Professor of Urology Emerita, Stanford University School of Medicine, Stanford, California

Urinary Tract Infections, Renal Abscess, and Other Complex Renal Infections

George Kelly Siberry MD, MPH, Medical Officer, Maternal Pediatric Infectious Disease Branch, Eunice Kennedy Shriver National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, Maryland

Management of HIV Infection

Jane D. Siegel MD, Former Professor of Pediatrics, Division of Infectious Diseases, University of Texas Southwestern Medical Center, Dallas, Texas

Pediatric Healthcare Epidemiology

Robert David Siegel MD, PhD, Professor of Microbiology and Immunology, Stanford University School of Medicine, Stanford, California

Classification of Human Viruses

Kari A. Simonsen MD, Associate Professor of Pediatrics and Public Health, Chief, Pediatric Infectious Diseases, University of Nebraska Medical Center, Omaha, Nebraska

Infectious Complications of Corticosteroid Therapy

Nalini Singh MD, MPH, Professor of Pediatrics, Global Health, and Epidemiology, George Washington University School of Medicine & Health Sciences; Division of Infectious Diseases, Children's National Health System, Washington, District of Columbia

Clostridium difficile

Upinder Singh MD, Associate Professor of Medicine and Microbiology and Immunology, Stanford University School of Medicine, Division Chief of Infectious Diseases and Geographic Medicine, Stanford University Medical Center, Stanford, California

Entamoeba histolytica (Amebiasis); *Other Entamoeba, Amebas, and Intestinal Flagellates*; *Naegleria fowleri*; *Acanthamoeba Species*

P. Brian Smith MD, MPH, MHS, Professor of Pediatrics, Division of Neonatology, Duke University Medical Center, Duke Clinical Research Institute, Durham, North Carolina

Candida Species

John D. Snyder MD †, Professor of Pediatrics, George Washington University School of Medicine & Health Sciences; Chief, Gastroenterology, Hepatology, and Nutrition, Children's National Health System, Washington, District of Columbia

Acute Hepatitis; *Chronic Hepatitis*

Eunkyung Song MD, Assistant Professor of Pediatrics, The Ohio State University College of Medicine; Division of Infectious Diseases, Nationwide Children's Hospital, Columbus, Ohio

Serratia Species

Jennifer L. Sorrell MD, Clinical Assistant Professor of Dermatology and Pediatrics, Departments of Dermatology and Pediatrics, Stanford University School of Medicine, Palo Alto, California

Papules, Nodules, and Ulcers

1

Principles of Epidemiology and Public Health

Lucy A. McNamara, Stacey W. Martin

Epidemiology is the study of the distribution and determinants of disease or other health-related states or events in specified populations and the application of this study to the control of health problems.[1] The key component of this definition is that epidemiology focuses on populations, an emphasis that distinguishes epidemiology from clinical case studies, which focus on individual subjects.

Health events can be characterized by their distribution (descriptive epidemiology) and by factors that influence their occurrence (analytic epidemiology). In both descriptive and analytic epidemiology, health-related questions are addressed using quantitative methods to identify patterns or associations from which inferences can be drawn and interventions developed, applied, and assessed.

Descriptive Epidemiology

Surveillance

The goals of descriptive epidemiology are to define the frequency of health-related events and determine their distribution by person, place, and time. The foundation of descriptive epidemiology is surveillance, or case detection. Retrospective surveillance identifies health events from existing data, such as clinical or laboratory records, hospital discharge data, and death certificates. Prospective surveillance identifies and collects information about cases as they occur, for example, through ongoing laboratory-based reporting.

With *passive surveillance,* case reports are supplied voluntarily by clinicians, laboratories, health departments, or other sources. The completeness and accuracy of passive reporting are affected by whether reporting is legally mandated, whether a definitive diagnosis can be established, illness severity, interest in and awareness of the medical condition among the public and the medical community, and whether a report will elicit a public health response. Because more severe illness is more likely to be diagnosed and reported, the severity and clinical spectrum of passively reported cases are likely to differ from those of all cases of an illness. Passively collected reports of nationally notifiable diseases are tabulated in the *Morbidity and Mortality Weekly Report* (http://www.cdc.gov/mmwr/).

In *active surveillance,* an effort is made to ascertain all cases of a condition occurring in a defined population. Active case finding can be prospective (through routine contacts with reporting sources), retrospective (through record audit), or both. Population-based active surveillance, in which all cases in a defined geographic area are identified and reported, provides the most complete and unbiased ascertainment of disease and is optimal for describing the rate of a disease and its clinical spectrum. By contrast, active surveillance conducted at only one or several participating facilities can yield biased information on disease frequency or spectrum based on the representativeness of the patient population and the size of the sample obtained.

Case Definition

Establishing a standard case definition is an important first step for surveillance and description of the epidemiology of a disease or health event.[2] Formulation of a case definition is important, particularly when laboratory diagnostic testing results are not definitive. More restrictive case definitions minimize misclassification, but they can exclude true cases and are most useful when investigating a newly recognized condition, in which the ability to determine etiology, pathogenesis, or risk factors is decreased by inclusion of noncases in the study population. A more inclusive definition can be important in an outbreak setting to detect potential cases for further investigation or when preventive interventions can be applied. Multiple research or public health objectives can be addressed by developing a tiered case definition that incorporates varying degrees of diagnostic certainty for definite and probable cases.

Sensitivity, Specificity, and Predictive Value

Sensitivity, specificity, and predictive values can be used to quantify the performance of a case definition or the results of a diagnostic test or algorithm (Table 1.1). Unlike sensitivity and specificity, predictive values vary with the prevalence of a condition within a population. Even with a highly specific diagnostic test, if a disease is uncommon among those people tested, a large proportion of positive test results will be false positive, and the positive predictive value will be low (Table 1.2). If the test is applied more selectively such that the proportion of people tested who truly have disease is greater, the test's predictive value will be improved. Thus, sensitivity and specificity are characteristics of the test, whereas predictive values depend both on test sensitivity and specificity and on the disease prevalence in the population in which the test is applied. Often, the sensitivity and specificity of a test are inversely related. Selecting the optimal balance of sensitivity and specificity depends on the purpose for which the test is used. Generally, a screening test should be highly sensitive, whereas a follow-up confirmatory test should be highly specific.

TABLE 1.1

Definitions and Formulas for the Calculation of Important Epidemiologic Parameters

Measures of test	*Sensitivity:* Proportion of	A/(A + C)	

accuracy	true positive (diseased) with a positive test result		 Disease No Disease Positive Test Negative Test A B C D
	Specificity: Proportion of true negative (nondiseased) with a negative test result	D/(B + D)	
	Positive predictive value (PPV): Proportion of positive test results that are true positives	A/(A + B)	
	Negative predictive value (NPV): Proportion of negative test results that are true negatives	D/(C + D)	
Measures of data dispersion and precision	*Variance:* Statistic describing variability among individual members of a population	$[1/(n-1)]\left[(x_1-\bar{x})^2+(x_2-\bar{x})^2+\ldots+(x_n-\bar{x})^2\right]$		Standard error (SE): Statistic describing the variability of sample-based point estimates (P) around the true population value being estimated	$\sqrt{\text{Variance}}$	
	Confidence interval: A range of values that is believed to contain the true value within a defined level of certainty	—	

	(usually 95%)		

TABLE 1.2

Positive and Negative Predictive Values for a Hypothetical Diagnostic Test Having a Sensitivity of 90% and a Specificity of 90%

Proportion With Condition	Positive Predictive Value	Negative Predictive Value
1%	8%	>99%
10%	50%	99%
20%	69%	97%
50%	90%	90%

Incidence and Prevalence

Characterizing disease frequency is one of the most important aspects of descriptive epidemiology. Frequency measures typically include a count of new or existing cases of disease as the numerator and a quantification of the population at risk as the denominator. *Cumulative incidence* is expressed as a proportion and describes the number of new cases of an illness occurring in a fixed at-risk population over a specified period of time, generally 1 year unless otherwise stated. *Incidence density* is the rate of new cases of disease in a dynamic at-risk population; the denominator typically is expressed as the population-time at-risk (e.g., person-time).

Because the occurrence of many infections varies with season, extrapolating annual incidence from cases detected during a short observation period can be inaccurate. In describing the risk of acquiring illness during a disease outbreak, the *attack rate,* defined as the number of new cases of disease occurring in a specified population and time period, is a useful measure. Finally, the *case-fatality rate*, or proportion of cases of a disease that result in death, is used to quantify the mortality resulting from a disease in a particular population and time period.

Prevalence refers to the proportion of the population having a condition at a specific point in time. As such, it is a better measure of disease burden for chronic conditions than is incidence or attack rate, which identify only new (incident) cases. Prevalent cases of disease can be ascertained in a cross-sectional survey, whereas determining incidence requires longitudinal surveillance. When disease prevalence (P) is low and incidence (I) and duration (D) are stable, prevalence is a function of disease incidence multiplied by its average duration ($P = I \times D$).

Describing Illness by Person, Place, and Time

Characterizing disease by person, place, and time is often useful. Demographic variables, including age, sex, socioeconomic status, and race or ethnicity, often are associated with the risk of disease. Describing a disease by place can help define risk groups, for example, when an illness is caused by an environmental exposure or is vector borne, or during an outbreak with a point source exposure. Time also is a useful descriptor of disease occurrence. Evaluating longterm (secular) trends provides information that can be used to identify emerging health problems or to assess the impact of prevention programs. The timing of illness in outbreaks can be displayed in an epidemic curve and can be useful in defining the mode of transmission of an infection or its incubation period and in assessing the effectiveness of control measures.

Analytic Epidemiology

Study Design

The goal of analytic studies is to identify predictors of an outcome. This goal can be addressed in experimental or epidemiologic (observational) studies. In addition, ecologic or trend studies can be used to assess predictors when the frequency or distribution of an outcome has changed over time or differs among populations.

In *experimental studies,* hypotheses are tested by systematically allocating an exposure of interest to subjects in separate groups to achieve the desired comparison. Such studies include randomized, controlled, double-blind treatment trials, as well as laboratory experiments. By carefully controlling study variables, investigators can restrict differences among groups and thereby increase the likelihood that the observed differences are a consequence of the specific factor being studied. Because experiments are prospective, the temporal sequence of exposure and outcome can be established, making it possible to define cause and effect.

By contrast, *epidemiologic studies* test hypotheses using observational methods to assess exposures and outcomes among individual subjects in populations and to identify statistical associations from which inferences regarding causation are drawn. Although observational studies cannot be controlled to the same degree as experiments, they are practical in circumstances in which exposures or behaviors cannot be assigned. Moreover, the results often are more generalizable to a real population having a wide range of attributes. The 3 basic types of observational studies are cohort studies, cross-sectional studies, and case-control studies (Table 1.3). Hybrid study designs, incorporating components of these 3 types, also have been developed.[3] In planning observational studies, care must be taken in the selection of participants to minimize the possibility of bias. Selection bias results when study subjects have differing probabilities of being selected and the probability of selection is related to the risk factors or outcomes under evaluation.

TABLE 1.3

Types of Observational Studies and Their Advantages and Disadvantages

Type of Study	Design and Characteristics	Advantages	Disadvantages
Cohort	Prospective or retrospective	Ideal for outbreak investigations in defined populations	Unsuited for rare diseases or those with long latency
	Select study group	Prospective design ensures that exposure preceded disease	Expensive
	Observe for exposures and disease	Selection of study group is unbiased by knowledge of disease status	Can require long follow-up periods
	Outcome measures used: Relative risk (RR) or hazard ratio (HR) of disease given exposure	RR and HR accurately describe risk given an exposure	Difficult to investigate multiple exposures
Cross-sectional	Nondirectional	Rapid, easy to perform, and inexpensive	Timing of exposure and disease can be difficult to determine
	Select study group	Ideal to determine knowledge, attitudes, and behaviors	Biases can affect recall of past exposures
	Determine exposure and disease status		
	Outcome measures used:		

	Prevalence ratio for disease given exposure		
Case-control	Retrospective	Rapid, easy to perform, and inexpensive	Timing of exposure and disease can be difficult to determine
	Identify cases with disease	Ideal for studying rare diseases, those with long latency, new diseases	Biases can occur in selecting cases and controls and determining exposures
	Identify controls without disease		OR only provides an estimate of the RR if disease is rare
	Determine exposures in cases and controls		
	Outcome measures used: Odds ratio (OR) for an exposure given disease		

In contrast to experimental or observational studies that analyze information about individual subjects, *ecologic studies* draw inferences from data on a population level. Inferences from ecologic studies must be made with caution because populations differ in multiple ways and because relationships observed on a population level do not necessarily apply on the individual level (a problem known as the *ecologic fallacy*). Because of these drawbacks, ecologic studies are suited best for generating hypotheses that can be tested using other study methods.

Cohort Studies

In a *cohort study,* subjects are categorized based on their exposure to a suspected risk factor and are observed for the development of disease. Associations between exposure and disease are expressed by the *relative risk* of disease, or *risk ratio,* in exposed and unexposed groups (Table 1.4). Cohort studies typically are prospective, with exposure defined before disease occurs. However, cohort studies also can be retrospective, in which the cohort is selected after the outcome has occurred. In this case, exposures are determined from existing records that preceded the outcome, and thus the directionality of the exposure-disease relationship is still forward. Characterizing exposures before development of disease is a major benefit of cohort studies because this approach minimizes selection bias and simplifies inference of cause and effect. Another advantage of cohort studies is that they can be used to assess multiple potential outcomes resulting from an exposure. However, in a cohort study it can be difficult to investigate multiple exposures as risk factors for a single outcome. Cohort studies also are impractical for studying rare diseases or conditions with a long latent period between exposure and the onset of clinical illness. In general, cohort studies are unsuited for investigating risk factors for new or rare diseases or for generating new hypotheses about possible exposure-disease relationships.

TABLE 1.4

Measures of Association, Risk, and Impact

Absolute measures of association and risk	*Absolute risk reduction* (ARR), *excess risk*, or *attributable risk:* Difference in the incidence of the outcome between exposed and unexposed	(A/(A + B)) – (C/(C + D))	 Disease No Disease Exposed A B Unexposed C D
	Number needed to treat (NNT): Number of individual subjects who must receive an intervention (or exposure) to prevent one negative outcome	1/ARR	
Relative measures of association and risk	*Relative risk* or *risk ratio* (RR): Risk (probability) of a health event in those with a given exposure divided by the risk in those without the exposure	$\frac{A/(A+B)}{C/(C+C)}$	
	Odds ratio (OR): Odds of a given exposure among those with a health event divided by odds of exposure among those without the health event	AD/BC	
Measure of impact	*Population attributable fraction:* The proportion of	$[P_e\ (RR-1)]/[1 + P_e\ (RR-1)]$ [Proportion exposed, P_e = (A	

	disease in a population that results from the specific exposure	+ B)/(A + B + C + D)]	
	Vaccine efficacy (VE): The percentage of reduction in incidence of a disease among persons who have received a vaccine compared with the incidence in persons who have not received the vaccine	(1 − RR) × 100 or (1 − OR) × 100	

Cohort studies provide data not only on whether an outcome occurs but also, for those experiencing the outcome, on when it occurs. Analysis of time-to-event data for outcomes such as death or illness is a powerful approach to assess or compare the impacts of preventive or therapeutic interventions. The probability of remaining event-free over time can be expressed in a *Kaplan-Meier survival curve* where the event-free probability is initially 1 and declines in a step-function as the outcomes of interest occur (Fig. 1.1A). Time-to-event data also can be displayed as the *cumulative hazard* of an event occurring among members of a cohort that increases from 0 at enrollment (Fig. 1.1B). These 2 approaches are related in that the hazard reflects the incident event rate, whereas survival reflects the cumulative nonoccurrence of that outcome.[4,5] With time-to-event analysis, the association between exposure and disease often is expressed as a hazard ratio. Like relative risk, hazard ratio is a comparative measure of risk between exposed and unexposed groups. The primary difference is that the hazard ratio compares event experience over the entire time period, whereas the relative risk compares event occurrence only at the study endpoint.[6]

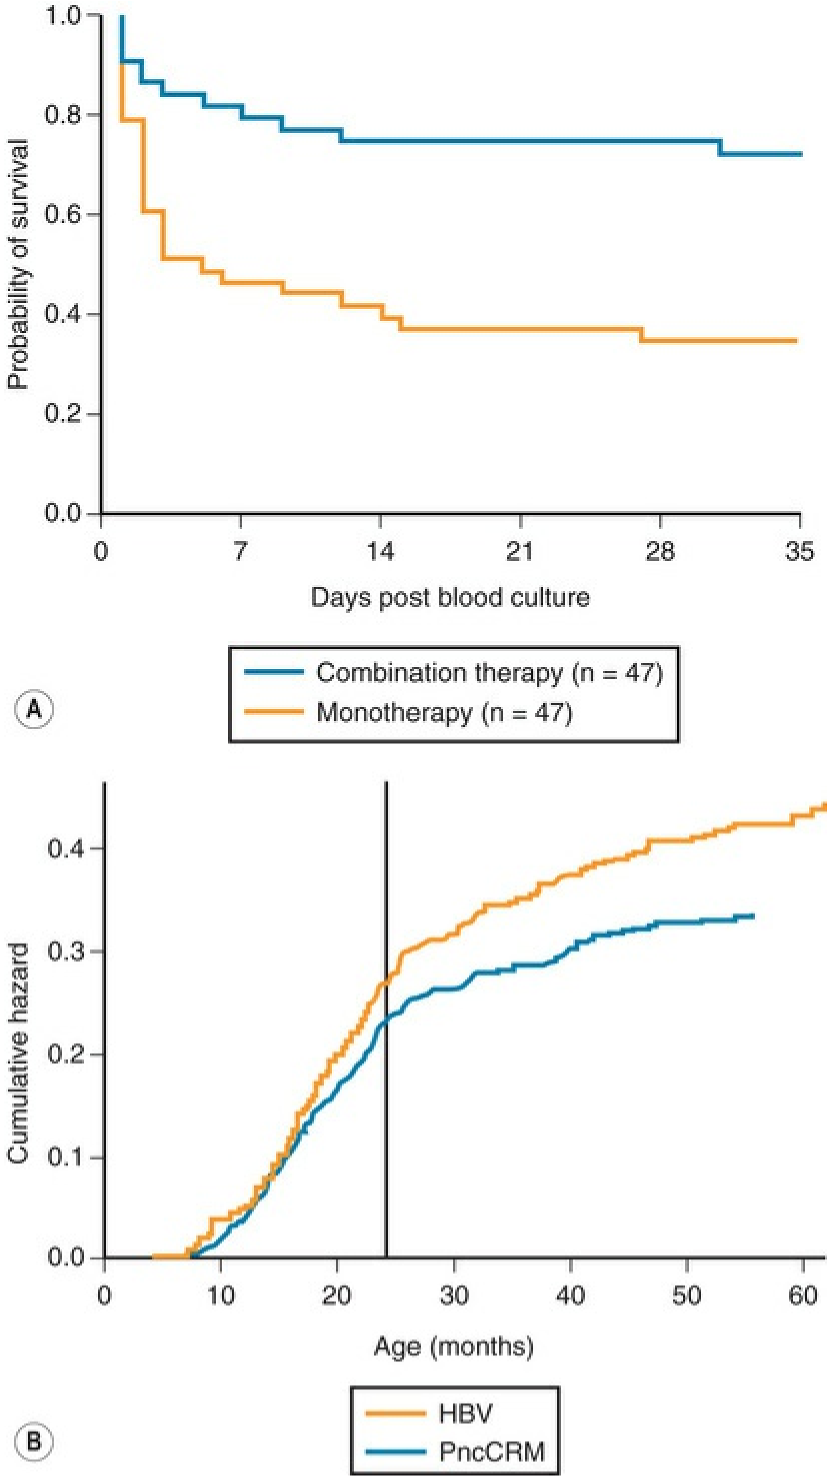

FIGURE 1.1 **Example of Kaplan-Meier and cumulative hazard curves. (A) Survival plot for critically ill patients with *Streptococcus pneumoniae* bacteremia treated with monotherapy or combination therapy. (B) Cumulative hazard of tympanostomy tube placement from 2 months until 4 to 5 years of age in children who received pneumococcal conjugate vaccine (PncCRM) or a control vaccine (hepatitis B vaccine [HBV]).** **([A] Redrawn from Baddour LM, Yu VL, Klugman KP, et al. Combination antibiotic therapy lowers mortality among severely ill patients with pneumococcal bacteremia. Am J Respir Crit Care Med 2004;170:440–444. [B] Redrawn from Palmu AAI, Verho J, Jokinen J, et al. The seven-valent pneumococcal conjugate vaccine reduced tympanostomy tube placement in children. Pediatr Infect Dis J 2004;23:732–738.)**

Cross-Sectional Studies

In a *cross-sectional study,* or survey, a sample is selected, and at a single point in time exposures and outcome are determined. Outcomes can include disease status or behaviors and beliefs, and multiple exposures can be evaluated as explanations for the outcome. Associations are characterized by the *prevalence ratio*, similar to the risk ratio in cohort studies. Because neither exposures nor outcomes are used in selection of the study group, prevalence is an estimate of that in the overall population from which the sample was drawn. National survey data characterizing health status, behaviors, and medical care are available from the National Center for Health Statistics (http://www.cdc.gov/nchs/index.htm).

Case-Control Studies

In a *case-control study,* the investigator identifies a group of people with a disease or outcome of interest (cases) and compares their exposures with those in a selected group of people who do not have disease (controls). Differences between the groups are expressed by an *odds ratio,* which compares the odds of an exposure in case and control groups (see Table 1.4). The odds ratio is not the same as a risk ratio; however, it provides an estimate of the risk ratio if the disease or outcome in question is rare. Case-control studies are retrospective in that disease status is known and serves as the basis for selecting the 2 comparison groups; exposures are then determined by reviewing available records or by interview.

A major advantage of case-control studies is their efficiency in studying uncommon diseases or diseases with a long latency. Case-control studies also can evaluate multiple exposures that may contribute to a single outcome; study subjects frequently can be identified from existing sources (e.g., hospital or laboratory records, disease registries, or surveillance reports) and, after identification of suitable control subjects, data on previous exposures can be collected rapidly. Case-control studies also have several drawbacks. Bias can be introduced during selection of cases and controls and in determining exposures retrospectively, and inferring causation from statistically significant associations can be complicated by difficulty in determining the temporal sequence of exposure and disease.

Causal Inference and the Impact of Bias

The impact of potential bias is particularly important in observational studies. The *validity* of a study is the degree to which inferences drawn from a study are warranted. *Internal validity* refers to the correctness of study conclusions for the population from which the study sample was drawn, whereas *external validity* refers to the extent to which the study results can be generalized beyond the population sampled. The validity of a study can be affected by bias, or *systematic error,* in selecting the study participants (sampling), in ascertaining their exposures, or in analyzing and interpreting study data. For errors to result in bias, they must be systematic, or directional. *Nonsystematic error* (random misclassification) decreases the ability of a study to identify a true association but does not result in detection of a spurious association.

Several sources of bias can occur in selection of study participants (Box 1.1).[7] *Diagnosis bias* results when persons with a given exposure are more likely to be diagnosed as having disease than are people without the exposure; this can occur because diagnostic testing is more likely to be done or because the interpretation of a test may be affected by knowledge of exposure status. For hospital-based studies, differential referral also can bias selection of a study sample. This bias would occur if, for example, the frequency of an exposure varied with socioeconomic status and a hospital predominantly admitted persons from either a high-income group or a low-income group. Bias also can occur when eligible subjects refused to participate in a study as cases or controls.

Box 1.1

Potential Sources of Bias in Observational Studies[a]

Bias in Case Ascertainment and Case/Control Selection

Surveillance bias: differential surveillance or reporting for exposed and unexposed

Diagnosis bias: differential use of diagnostic tests in exposed and unexposed

Referral bias: differential admission to hospital based on an exposure or a variable associated with exposure

Selection bias: differential sampling of cases based on an exposure or a variable associated with exposure

Nonresponse bias: differential outcome or exposures of responders and nonresponders

Survival bias: differential exposures between those who survive to be included in a study and those who die following an illness

Misclassification bias: systematic error in classification of disease status

Bias in Estimation of Exposure

Recall bias: differential recall of exposures based on disease status

Interviewer bias: differential ascertainment of exposures based on disease status

Misclassification bias: systematic errors in measurement or classification of exposure

---

[a] A more complete listing is provided by Sackett.[7]

Determination of exposures can be affected by several types of bias. Recall of exposures can be different for persons who have had an illness compared with people who were well. This bias occurs in either direction: patients may be more likely to remember an exposure that they associate with their illness (e.g., what was eaten before an episode of diarrhea) or less likely to recall an exposure if a severe illness affected memory. Interviewers can introduce bias by questioning cases and controls differently about their exposures. Misclassification of exposures can result from errors in measurement such as can occur with the use of an inaccurate laboratory test. Although systematic misclassification can result in bias, misclassification of exposure often is random rather than systematic.

Even a carefully designed study that minimizes potential biases can lead to erroneous causal inferences. An exposure can falsely appear to be associated with disease because it is closely linked to the true, but undetermined, risk factor. Race often is found to be associated with the risk of a disease, whereas the true risk factor may be an unmeasured variable that is linked to race, such as socioeconomic status. The risk of making incorrect inferences can be minimized by considering certain general criteria for establishing causation. These criteria include the strength of an association, the presence of a dose-response effect, a clear temporal sequence of exposure to disease, the consistency of findings with those of other studies, and the biologic plausibility of the hypothesis.[8]

Statistical Analysis

Characteristics of Populations and Samples

Whereas epidemiologic analysis seeks to make valid conclusions about populations, the entire population rarely is included in a study. An assumption underlying statistical analysis is that the sample evaluated was selected randomly from the population. Often, this criterion is not met and calls into question the appropriateness and interpretation of statistical analyses.

The mean, median, and mode describe central values for samples and populations. The arithmetic *mean* is the average, determined by summing individual values and dividing by the sample size. When data are not normally distributed (skewed), calculation of a geometric mean can limit the impact of outlying values. The geometric mean is calculated by taking the nth root of the *product* of all the individual values, where n is the total number of individual values. For example, immunogenicity of vaccines is usually expressed by the geometric mean titer. The *median,* or middle value, is another way to describe nonnormally distributed data. The *mode,* or most commonly occurring value in a sample, rarely is used.

Several measures can be used to describe the variability in a sample. The *range* describes the difference between the highest and lowest value, whereas the *interquartile range* defines the difference between the 25th and 75th percentiles. Variation among individual elements most often is characterized by the variance or standard deviation. The *variance* is the mean of the squared deviation of each observation from the sample's mean. The *standard deviation* is the square root of the variance (see Table 1.1). For a normally distributed population, 68% of values fall within 1 standard deviation of the mean, and 95% of values fall within 1.96 standard deviations. The *standard error* represents a type of standard deviation and is used to describe the standard deviation of an estimate (e.g., mean, odds ratio, relative risk).

When analyzing a sample, the mean or other statistics describing the sample represent a *point estimate* of that parameter for the entire population. If another random sample were drawn from the same population, the point estimate for the parameter of interest likely would be different, depending on the variability in the population and the sample size selected. A *confidence interval* defines a range of values that includes the true population value, within a defined level of certainty. Most often, the 95% confidence interval is presented (see Table 1.1).

Absolute and Relative Measures of Association

Measures of association are used to assess the strength of an association between an exposure and an outcome. In a cohort study, the *absolute risk reduction* (also known as *excess risk, attributable risk,* or *risk difference*) is the difference in the incidence of the outcome between exposed and unexposed subjects. The *number needed to treat* (NNT) is a measure of the number of individual subjects who must receive a treatment to prevent a single negative outcome and is calculated as the reciprocal of the *absolute risk reduction*. In addition to absolute measures, relative measures also are useful for describing the strength of an association. In a cohort study or survey, the relative risk or risk ratio compares the risk of disease for subjects with versus subjects without an exposure (see Table 1.4). In case-control studies, association is assessed by the odds ratio, which compares the odds of exposure among subjects with and without a disease or health outcome; when disease is uncommon (<10%) in both exposed and unexposed groups, the odds ratio approximates the relative risk. For time-to-event analyses, the comparative risk is expressed as the *hazard ratio.* Odds ratios, relative risks, and hazard ratios greater than 1 signify increased risk given exposure, and values less than 1 suggest that exposure decreases the risk of an outcome. Because observational studies generally do not include all members of a population, these measures of association represent an estimate of the true value within the entire population. Statistical analyses can help guide investigators in making causal inferences based on point estimates of these measures of association.

Statistical Significance

Statistical tests are applied to assess the likelihood that the study results were obtained by chance alone rather than representing a true difference within the population. Most investigators consider a P value <0.05 as being *statistically significant*, indicating a less than 5% risk that the observed association is the result of chance alone (designated a *type I error*, the probability of which is the *alpha level*). Although use of this cutoff for significance testing has become conventional, ignoring higher P values can lead to missing a real and important association, whereas blind faith in the significance of lower P values can lead to erroneous conclusions. Statistical testing should contribute to, but not replace, criteria for evaluating possible causation.

Statistical significance also can be defined based on 95% confidence intervals, which approximately correspond to a P value of 0.05. An odds ratio, relative risk, or hazard ratio is considered statistically significant if the 95% confidence interval does not include 1. An advantage of using confidence intervals to define statistical significance is that they provide information on whether a finding is statistically significant and on the possible range of values for the point estimate in the population, with 95% certainty.

One pitfall in interpreting statistical significance is ignoring the *magnitude* of an effect in favor of its "significance." A very large study can identify as significant a small, perhaps trivial, difference among study groups. Some epidemiologists have proposed that, despite statistical significance, odds ratios less than 2 or 3 in an observational study should not be interpreted because unidentified bias or confounding could have accounted for a difference of this magnitude.[9] Conversely, the relative risk or odds ratio associating an exposure and outcome can be large, but if the exposure is uncommon in both groups, it cannot explain most cases of illness. The public health importance of an exposure can be described by the *population-attributable fraction*, or the proportion of the disease in a population that is related to the exposure of interest.

Sample Size

A study can fail to identify a true risk factor as statistically significant because the sample size was too small (designated a *type II error,* the probability of which is the *beta level*). Statistical power is defined as 1 − β and is the complement of type II error; that is, power is the probability of correctly identifying a difference of specified size among groups, if such a difference truly exists. The problem of inadequate sample size in clinical studies was highlighted in an analysis of “negative” randomized controlled trials reported in 3 leading medical journals between 1975 and 1990. Of 70 reports, only 16% and 36% had sufficient statistical power (80%) to detect a true 25% or 50% relative difference, respectively, among treatment groups.[10]

In calculating sample sizes for testing hypotheses, investigators must select type I and type II errors and define the magnitude of the difference that is deemed clinically important. Often, the type II error is set at 0.2, indicating acceptance of a 20% likelihood that a true difference exists but would not be identified by the study. Sample size calculations can be performed using a range of computer software. The program Epi-Info can be used to perform sample size calculations as well as other statistical functions and is available at no charge from the Centers for Disease Control and Prevention (www.cdc.gov/epiinfo/).

Ensuring an adequate sample size is particularly important for studies attempting to prove *equivalence* or *noninferiority* of a new treatment compared with standard therapy. Food and Drug Administration guidance recommends that noninferiority trials adopt a null hypothesis that a difference exists among treatments; this hypothesis is rejected if the lower 95% confidence limit for the new treatment is within a specified margin of the point estimate for standard therapy. Because the null hypotheses can never be proven or accepted, the failure to reject a null hypothesis of no difference among treatments or exposure does not prove equivalence. The importance of this distinction is illustrated by an analysis of 25 studies claiming equivalence of therapies for pediatric bacterial meningitis. Twenty-three studies claimed equivalence based on a failure to detect a significant difference among treatment groups.

However, only 3 of these trials could exclude a 10% difference in mortality, thus showing that many studies potentially missed a clinically significant difference.[11]

In some situations, an investigator would want to detect a significant difference among study groups as soon as possible, for example, when a therapeutic or preventive intervention could be applied once a risk group is identified or when concerns exist about the safety of a drug or vaccine. One approach to this situation is to include in the study design an *interim analysis* after a specified number of subjects are evaluated. Because the likelihood of identifying chance differences as significant increases with the number of analyses, it is recommended that the threshold for defining statistical significance should become more stringent as the number of planned analyses increases.[12] If each interim analysis can lead the investigators to stop the trial, this study design is considered a group sequential method.[13] Another example of a group sequential design is when concordance or discordance in outcome is tabulated for each matched set exposed to alternate treatments. Results for each set are plotted on a graph, and data collection continues until a preset threshold for a significant difference among study groups is crossed or no significant difference is detected at a given power.[12]

Statistical Inference

Statistical testing is used to determine the significance of differences among study groups, and thus it provides guidance on whether to accept or reject the null hypothesis. Although providing details of specific statistical tests is outside the scope of this chapter, Table 1.5 gives examples of statistical tests that can be applied in analyzing different types of exposure and outcome variables.

TABLE 1.5

Types of Statistical Tests Used to Evaluate the Significance of Associations Among Categorical and Continuous Variables

Independent Variable (Exposure, Risk Factor)	**Dependent Variable (Disease, Outcome)**	
	Categorical and Dichotomous	**Continuous**
CATEGORICAL		
Dichotomous	Chi-square test	Student t-test (parametric)

	Fisher exact test	Wilcoxon rank sum test (nonparametric)
>2 categories	Chi-square test	Analysis of variance (parametric)
		Kruskal-Wallis test (nonparametric)
CONTINUOUS		
	Logistic regression	Linear regression
		Correlation (Pearson: parametric; Spearman: nonparametric)

Using appropriate analytic and statistical methods is important in identifying significant predictors of an outcome (i.e., risk factors) correctly. *Confounding variables* are associated with the disease of interest and with other exposure variables that are associated with the disease and are not part of the causal pathway (Fig. 1.2). For example, if recent antimicrobial use is associated with childcare attendance, failure to adjust for recent antimicrobial use as a confounding variable could result in overestimating the relationship between childcare and antibiotic-resistant pneumococcal carriage. *Effect modifiers* interact with risk factors to affect their impact on outcome but may or may not themselves affect outcome. Frequently, age is an effect modifier, with an exposure associated significantly with an outcome in one age group but not in another.

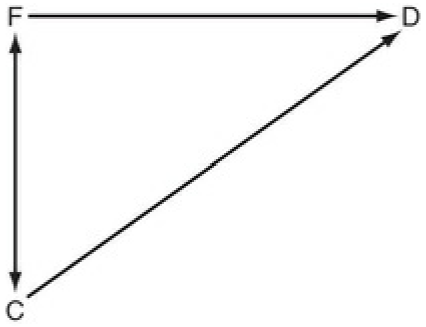

FIGURE 1.2 Path diagram illustrating associations among a confounding variable (*C*), another risk factor (*F*), and the disease outcome (*D*).

Several approaches are used to control for confounding variables and effect modifiers. In study design, an extraneous variable can be controlled for by randomization, restricting sampling to one category of the variable or by *frequency matching* to obtain similar proportions of cases and controls in each stratum of the variable. A more extreme form of matching is to select control subjects who are similar to individual cases for extraneous variables (e.g., age, sex, underlying disease) and to analyze whether exposures are concordant or discordant within matched sets. A newer approach to study design is the *case-crossover*[14] or *case series*[15] analysis. In this method, exposures occurring in a defined risk period before the outcome are compared with exposures occurring outside the risk window for the same individual subjects. This approach has been adapted to the study of adverse events after vaccination. If the vaccine causes the event, the rate of the event will be greater within a defined risk window than predicted by chance alone based on the expected distribution of the event.[16] The strength of this approach is that each subject, or case, serves as his or her own control, thereby decreasing confounding.

At the analysis stage, the impact of confounding variables and effect modifiers can be limited by performing a stratified analysis or using a multivariable model. In a *stratified analysis,* the possible association between a risk factor and an outcome is determined separately within different categories, or strata, of the extraneous variable. Stratum-specific estimates can be combined into a single estimate using an appropriate statistical test (e.g., a *Mantel-Haenszel odds ratio*). If a stratification variable is an effect modifier, the relative risk or odds ratio will differ substantially among the strata; for example, an exposure can be a strong risk factor in one age group but not another. In this setting, a summary statistic should not be presented, and results for each stratum should be presented separately. When the extraneous variable is confounding, an unstratified analysis can identify an exposure as a significant risk factor, whereas stratifying analysis by the confounding variable abolishes the apparent association in each stratum and indicates that the exposure is not an independent risk factor for disease.

Because stratified analyses become confusing rapidly as the number of strata increases, techniques of *mathematical modeling* have been developed that permit simultaneous control of multiple variables. Significant risk factors determined in a *multivariable model* are interpreted as each contributing independently and significantly to the outcome, thus controlling for confounding. Effect modification can be taken into account by including terms expressing the interaction between a risk factor and effect modifier in the model. Various multivariable models are appropriate for discrete, continuous, and time-dependent outcomes. A limitation of multivariable modeling is *multicollinearity,* which occurs when 2 or more explanatory variables of interest are highly correlated, and it can result in inaccurate measures of association and decreased statistical power. The risk of multicollinearity can be reduced by assessing correlations among potential risk factors and selecting which variables to include in the model. Various methods to identify and minimize multicollinearity have been developed.[17]

Vaccine Efficacy Studies

Most prelicensure efficacy studies are experimental, randomized, double-blind, controlled trials in which *vaccine efficacy* (VE) is calculated by comparing the attack rates (AR) for disease in the vaccinated and unvaccinated groups: $\text{VE (\%)} = (\text{AR unvaccinated} - \text{AR vaccinated}) / \text{AR unvaccinated}) \times 100$; or $(1 - \text{RR}) \times 100$.

After licensure, conducting controlled studies, which requires withholding vaccine from a control group, is no longer ethical. Therefore further studies of efficacy must be observational rather than experimental, by comparing persons who have chosen to be immunized with those who have not. In *case-control efficacy studies,* vaccination status of persons with disease is compared with vaccination status of healthy control subjects. The number of vaccinated and unvaccinated cases and controls is included in a 2×2 table, and vaccine efficacy is calculated as 1 minus the odds ratio: $\text{VE (\%)} = (1 - \text{OR}) \times 100$. When the proportion of cases vaccinated is less than the proportion of vaccinated controls, the odds ratio is <1, and the point estimate for efficacy indicates that immunization is protective. The precision of the estimate is expressed by the 95% confidence interval. A lower 95% confidence limit that is greater than 0% indicates statistically significant protection; often investigators set power of vaccine efficacy studies so that the expected lower confidence limit is much greater than 0 and consistent with meaningful levels of protection. The most important component of a case-control efficacy study is selecting control subjects who have the same opportunity for immunization as do cases. If cases have less opportunity to be immunized, results will be biased toward showing protection. Factors such as low socioeconomic status, which can increase the risk of disease and decrease the chance of being immunized, are potential confounding variables and can be controlled for by matching control subjects to cases for those factors.

Cohort studies also can be used to determine vaccine efficacy after licensure. A study design called the *indirect-cohort method* was developed by researchers at the Centers for Disease Control and Prevention to evaluate the efficacy of the pneumococcal polysaccharide vaccine by using data collected by disease surveillance.[18] The study cohort included persons identified with invasive pneumococcal infections. The study hypothesis was that if vaccine was protective, the proportion of vaccinated persons infected with pneumococcal serotypes that are included in the vaccine formulation would be less than the proportion of unvaccinated persons infected with vaccine-type strains. Vaccine efficacy was calculated from the relative serotype distributions overall and for each individual serotype. In a study of pneumococcal polysaccharide vaccine efficacy that used this approach, the point estimate of efficacy for preventing invasive infection was 57% (95% confidence interval, 45% to 66%)[19]; this estimate is similar to that obtained in a case-control efficacy study.[20]

Disease Control and Public Health Policy

Outbreak Investigations

Outbreak investigations require knowledge of disease transmission and use of descriptive and analytic epidemiologic tools. Possible outbreaks can be identified from surveillance data showing an increased rate of an infection or an unusual clustering of infection in person, place, and time. Comparing the incidence rate of disease with a baseline rate from a previous period is helpful in validating the occurrence of an outbreak. Other explanations for changes in the apparent rate of disease occurrence, such as diagnostic error, seasonal variations, and changes in reporting, must be considered. Using sensitive molecular methods to assess similarities among isolates from cases can be helpful in documenting that an apparent cluster of cases represents an outbreak because most outbreaks are caused by a single strain.

After establishing the presence of an outbreak, the next steps of an investigation are to develop a case definition, identify cases, and characterize the descriptive epidemiology. An *epidemic curve* depicts the number of cases over time and can provide information on possible transmission. In an outbreak with a *point source exposure,* an index case may be identified, with other cases occurring after an incubation period or at multiples of an incubation period (Fig. 1.3). Plotting the location of cases on a spot map can be helpful in determining possible exposures. Describing patients' characteristics can be important in identifying at-risk populations for further investigation or targeting control measures, as well as for developing hypotheses that can be investigated in an analytic study.

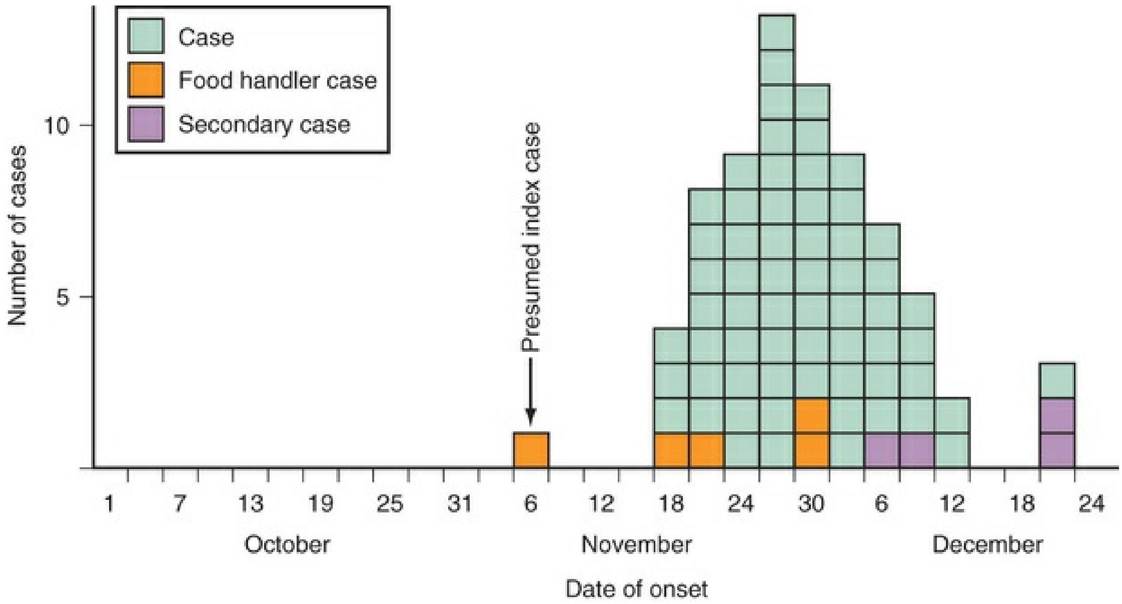

FIGURE 1.3 **Example of an epidemic curve for a common source outbreak with continuous exposure. Cases of hepatitis A by date of onset in Fayetteville, Arkansas, from November to December 1979.**

(From Centers for Disease Control and Prevention, unpublished data.)

Not all outbreaks can be traced to a point source exposure. Outbreaks and epidemics also can result from increased transmission of an *endemic* disease (i.e., a disease or condition that normally occurs in a specific population or area). In this situation it can be challenging to determine when an increase in disease constitutes an outbreak rather than a normal fluctuation in disease incidence. To determine whether an outbreak is occurring, the current incidence of the disease must be compared with the baseline disease incidence in that area. Often, no standard definition exists for when an increase in endemic disease incidence constitutes an outbreak or epidemic. For instance, in US pertussis epidemics the threshold for declaring an epidemic has varied by state. In California in 2010 and 2014, an epidemic was declared when the statewide case counts had reached 5 times the number of cases observed in a year with baseline pertussis incidence. By contrast, in Washington State in 2012, an epidemic was declared when the incidence of pertussis reached 2 standard deviations above the statewide 10-year average (Fig. 1.4).

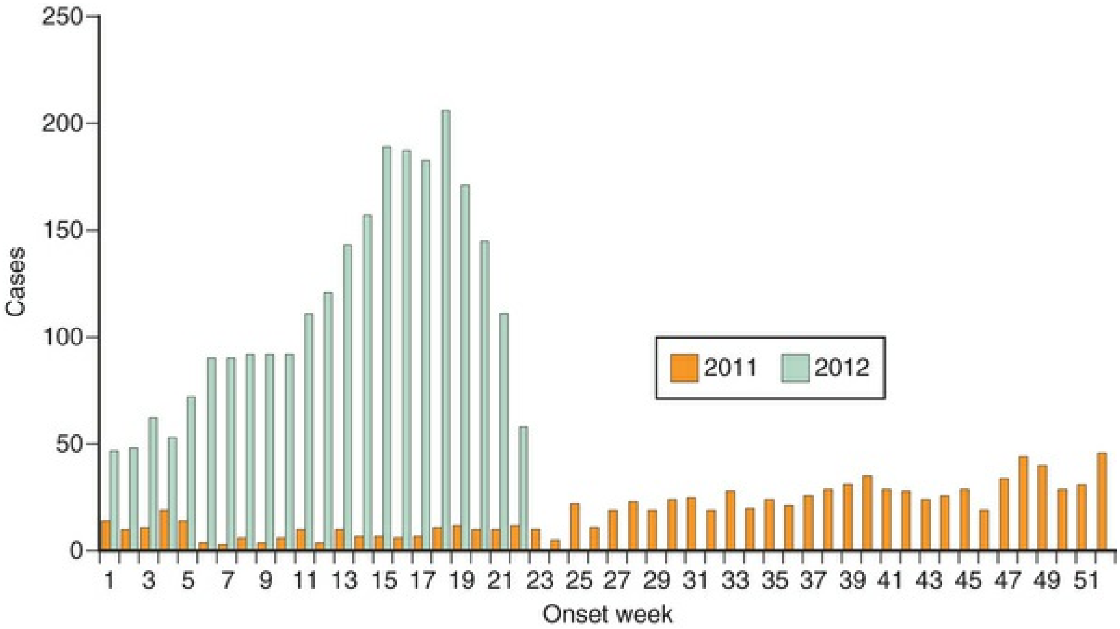

FIGURE 1.4 **Example of an epidemic curve for an epidemic of an endemic disease. Reported confirmed and probable pertussis cases by week of onset in Washington State, from January 1, 2011 to June 16, 2012.** (Redrawn from Centers for Disease Control and Prevention. Pertussis epidemic — Washington, 2012. MMWR Morb Mortal Wkly Rep 2012;61:517–522.)

Cohort studies are optimal for investigating outbreaks that occur in small, well-defined populations, including in schools, childcare settings, social gatherings, and hospitals. In populations that are not well defined, a case-control study is the most feasible approach. It is important to select control subjects who had an opportunity equal to that of cases for exposure to potential risk factors and development of disease. When the number of cases is relatively small, enrolling multiple control subjects per case increases the power of the study to find significant risk factors. After a standard questionnaire is administered, significant risk factors are determined by comparing exposures of cases and controls. The results of analyses can lead to inferences of causation and development of prevention and control strategies or to further hypotheses that can be evaluated later. The impact of intervention can be determined by ongoing surveillance and continued plotting of additional cases on the epidemic curve.

Impact and Economic Analysis of Disease Prevention

Assessing health and economic impacts of public health interventions is important in developing or supporting policy decisions. Health impacts can be expressed directly as cases of disease, deaths, and sequelae prevented. Vaccine efficacy is a specific example of the *prevented fraction* (PF), where $\mathrm{PF} = P\,(1 - \mathrm{RR})$, with P representing the proportion exposed to an intervention. Secondary measures of health impact include *years of potential life lost (YPLLs)* or *quality-adjusted life-years (QALYs)* lost, which quantify the impact of death, or death and disability, respectively, based on the age at which these events occur.[21] A measure of the efficiency of an intervention is the *number needed to treat,* which describes how many persons must be exposed to an intervention to avoid a single case of adverse health outcome.

Cost-effectiveness analyses determine the cost per health outcome achieved, such as the cost per death or complication averted, and it permits comparison of an intervention with other potential users of resources. In a cost-effectiveness formula, costs appear in the numerator, and health benefits appear in the denominator. The numerator includes expenditures for the prevention program from which cost savings occurring with disease prevention are subtracted. In addition to direct costs averted (e.g., savings from decreased medical care), indirect cost savings occur from increased productivity of people who do not become ill or miss time from work while receiving care or caring for ill family members. *Cost-utility* calculations are similar to cost-effectiveness but assess cost per quality-adjusted life-years saved or years of potential life lost averted.

Cost-benefit analyses differ from cost-effectiveness analyses in that the calculation is made entirely in economic terms. Health benefits are assigned an economic value, and expenditures are compared with savings. One problem with this approach lies in the difficulty of assigning an economic value to a health effect. For example, the value of a life saved may be quantified as the estimated value of a person's earnings over his or her lifetime, forgone earnings as a result of premature death, or by a standard amount; both economic and ethical issues can be raised by the choice of approach. Because the parameters used in economic analyses often are uncertain or based on limited data, and because choices made by the investigator (e.g., regarding the value of life) can be influential to the analysis, *sensitivity analyses* often are performed in which parameters are varied across a range of potential values. In addition to defining a range of possible economic outcomes, sensitivity analyses can identify the factors that most strongly influence the results, thus elucidating where further studies may be important.

Evaluating the Medical Literature

Steps in reviewing published medical research are shown in Box 1.2.[22] The ability to assess published studies carefully often is limited by the information presented in the report. To improve reporting of randomized controlled trials, a group of investigators and editors developed the Consolidated Standards of Reporting Trials (CONSORT)[23] (http://www.consort-statement.org/) and later extended these recommendations to reporting randomized trials of noninferiority and equivalences.[24] Reporting often still does not adhere to the quality standards proposed.[25,26] Although the guidelines refer to experimental rather than observational studies, most criteria apply to observational studies as well.

Box 1.2

Steps in the Critical Evaluation of Epidemiologic Literature

1. Consider the research hypothesis

2. Consider the study design

- Type of study

- Selection of study participants
- Selection and definition of outcome variables
- Selection and definition of exposure (predictor) variables
- Sample size and power

3. Consider the analysis

- Complete accounting of study subjects and outcomes
- Appropriateness of statistical tests
- Potential sources and impact of bias
- Potential impact of confounding and effect modification

4. Consider the interpretation of results

- Magnitude and importance of associations
- Study limitations
- Ability to make causal inferences

From Greenberg RS. Medical Epidemiology. Norwalk, CT, Appleton and Lange, 1993.

In assessing the medical literature, it is important to examine all published work on a particular topic rather than relying on a single report and to evaluate the strength of the combined evidence from these reports. One framework for evaluating the literature on a topic is the Grading of Recommendations Assessment, Development and Evaluation (GRADE) approach, adopted by the US Advisory Committee on Immunization Practices (ACIP) in 2010 (www.cdc.gov/vaccines/acip/recs/GRADE/about-grade.html). In GRADE, the strength of evidence for the relationship between a particular intervention or exposure and an outcome is categorized into 4 hierarchical levels, from greatest to least[27]:

1. Randomized controlled trials, or overwhelming evidence from observational studies

2. Randomized controlled trials with important limitations, or exceptionally strong evidence from observational studies

3. Observational studies, or randomized controlled trials with notable limitations

4. Clinical experience and observations, observational studies with important limitations, or randomized controlled trials with several major limitations

To minimize *publication bias* (i.e., the tendency to submit or publish reports of effectiveness versus noneffectiveness of a treatment), many countries require all clinical trials to be officially registered so that a record shows that the study was conducted even if the results are never published. Reviewing information on all registered clinical trials on a topic in addition to reviewing the published literature can provide a more complete picture of the effect of a particular intervention or exposure. In the United States, all clinical trials must be registered at clinicaltrials.gov; similar sites exist for other countries.

Understanding a Medical or Epidemiologic Study

Assessing the *research hypothesis* allows readers to determine the relevance of the study to their practice and to judge whether the analyses were done to test the hypothesis or to identify other associations of interest. The ability to make causal inferences from a confirmatory study that tests a single hypothesis is greater than from an exploratory study in which multiple exposures are considered as potential explanations for an outcome.

Several components of *study design* are important to consider. Details should be presented regarding the criteria for selecting the cohort or cases and controls. *Exposure* and *outcome variables* should be clearly defined, and the potential for misclassification and its impact should be considered. Quantifying exposure can be important to establish a dose-response relationship. S*ample size estimates* should be presented, making clear the magnitude of difference among study groups considered clinically meaningful and the type I and type II error levels.

In the *analysis*, it is important that outcomes for all study subjects are reported, even if that outcome is "lost to follow-up." *Intent-to-treat* analyses consider outcomes for all enrolled subjects, whether or not they completed the therapy (e.g., subjects who were nonadherent to therapy or who received only part of a vaccination series). By contrast, *per protocol* analyses include only those subjects who followed the study protocol throughout the full study duration. Usually, an intent-to-treat analysis is considered more conservative than a per protocol analysis, but this is not necessarily the case for noninferiority trials.

The appropriateness of the statistical tests should be assessed; for example, if data are not normally distributed, they can be transformed to a scale that is more normally distributed (e.g., geometric mean titers), or nonparametric statistical tests should be used. In assessing a multivariable model, the reader should critically evaluate the type of model chosen, the variables included, and whether interaction terms were considered. Missing data pose a particular problem in modeling in that study subjects can be included only if data are available for each variable in the model; thus the power of a multivariate model can be much less than that predicted in a sample size calculation.

Bias can have an important impact on study results and must be carefully considered. Approaches to minimize bias should be described clearly. The direction and potential magnitude of remaining bias should be estimated and its impact on results considered. Potential confounding, the presence of important unmeasured variables, and possible effect modification can have a major impact on the results. Investigators should openly discuss the potential limitations of the investigation and describe the strategies applied to overcome those limitations.

Interpretation of study results includes assessing the magnitude of the associations, their relevance to practice, and the likelihood that the relationships observed are causal. The importance of an exposure in explaining an outcome can be expressed by the attributable proportion. However, the *external validity* of the results and the potential impact on one's own patient population still must be assessed.

Pediatric Healthcare Epidemiology

Jane D. Siegel, Judith A. Guzman-Cottrill

The reduction of healthcare-associated infections (HAIs) is an important component of patient safety programs. Five of the 16 Hospital National Patient Safety Goals for 2016 of The Joint Commission (formerly the Joint Commission on Accreditation of Healthcare Organizations) target prevention of HAIs.[1] Hospitals have learned from high-reliability organizations (e.g., the aviation industry) the importance of adopting changes that include the leadership's commitment to achieving zero patient harm, a fully functional culture of safety throughout the organization, and the widespread deployment of highly effective process improvement tools.[2] Involvement of new stakeholders for improving patient safety and outcomes related to HAIs (e.g., Children's Hospitals' Solutions for Patient Safety, Children's Hospital Association, individual states' mandatory HAI public reporting programs, the Centers for Medicare and Medicaid Services, The Joint Commission) has broadened the arena for HAI prevention efforts. Knowledge of the complexities of prevention and control of HAIs in children is critical to many different leaders of children's healthcare facilities. One framework for patient safety in children's hospitals that includes infection prevention and control (IPC) was developed by the Ohio Children's Hospital Solutions collaborative and demonstrates the effectiveness of hospitalwide collaboration.[3] As more disciplines in healthcare become engaged in prevention of

HAIs as well as antimicrobial stewardship, it is the responsibility of the healthcare epidemiologist and the IPC staff (infection preventionists, healthcare epidemiologists) to educate the facility leadership on the discipline of IPC.

IPC for the pediatric population is a unique discipline that requires understanding of various host factors, sources of infection, routes of transmission, behaviors required for care of infants and children, pathogens and their virulence factors, treatments, preventive therapies, and behavioral theory. Although the term *nosocomial* still applies to infections that are acquired in acute care hospitals, the more general term, *healthcare-associated infections* (HAIs), is preferred because much care of high-risk patients, including patients with medical devices (e.g., central venous catheters, ventilators, ventricular shunts, peritoneal dialysis catheters), has shifted to ambulatory settings, rehabilitation or chronic care facilities, and the home; thus, the geographic location of acquisition of the infection often cannot be determined.

The principles of transmission of infectious agents in healthcare settings and recommendations for prevention are reviewed in the Healthcare and Infection Control Practices Advisory Committee (HICPAC) Guideline for Isolation Precautions: Preventing Transmission of Infectious Agents in Healthcare Settings, 2007[4] and in the Management of Multidrug Resistant Organisms in Healthcare Settings, 2006 document.[5] As new pathogens emerge, epidemiologists will continue to learn more about preventing transmission; therefore, for such pathogens, the most up-to-date guidance posted on the Centers for Disease Control and Prevention (CDC) or the World Health Organization (WHO) website should be consulted. The experience treating Ebola virus disease (EVD) in the United States in 2014 is the most recent example of changes in the usual infection prevention paradigm that were required, with emphasis on the hierarchy of controls[6] and donning and doffing of personal protective equipment (PPE) with trained observers.[7] A detailed discussion of HAIs can be found in Chapters 99 and 100. This chapter focuses on the components of an effective pediatric hospital epidemiology program.

Risk Factors for Healthcare-

Associated Infections in Children

Unique aspects of HAIs in children are summarized in the following sections. Specific risks and pathogens are addressed in several other chapters in this textbook.

Host or *Intrinsic* Factors

Intensive care units (ICUs), oncology services, and gastroenterology services caring for patients with short gut syndrome who are dependent on total parenteral nutrition (and lipids) have the highest rates of bacterial and fungal infection associated with central venous catheters. A newer definition of mucosal barrier injury laboratory-confirmed bloodstream infection (MBI-LCBI) currently is used by the National Healthcare Safety Network (NHSN) of the CDC to distinguish bacteremia that represents translocation of gut microorganisms related to mucosal barrier injury in patients with oncologic conditions, hematopoietic stem cell transplantation (HSCT), and intestinal failure from bacteremia associated with central venous catheters.[8] HAIs can result in substantial morbidity and mortality, as well as lifetime physical, neurologic, and developmental disabilities. Host (i.e., intrinsic) factors that make children particularly vulnerable to infection include immaturity of the immune system, congenital abnormalities, and congenital or acquired immunodeficiencies. Children with congenital anomalies have a high risk of HAI if their unusual anatomic features predispose them to contamination of normally sterile sites. Moreover, these children require prolonged and repeated hospitalizations, undergo many complex surgical procedures, and have extended exposure to invasive supportive and monitoring equipment.

Innate deficiencies of the immune system in prematurely born infants, who may be hospitalized for prolonged periods and exposed to intensive monitoring, supportive therapies, and invasive procedures, contribute to the relatively high rates of infection in the neonatal ICU (NICU). All components of the immune system are compromised in neonates, and the degree of deficiency is proportional inversely to gestational age (see Chapter 9). The underdeveloped skin of the very low birth weight (<1000 g) infant provides another mode of pathogen entry.

Populations of immunosuppressed children have expanded with the advent of more intense immunosuppressive therapeutic regimens used for oncologic conditions, HSCT, solid-organ transplantation, and rheumatologic conditions and inflammatory bowel disease for which immunosuppressive agents and tumor necrosis factor-α–inhibiting agents (infliximab [Remicade]) and other immune modulators are used. Genetic mutations in the genes for the transmembrane conductance regulator (CFTR) in children with cystic fibrosis result in thick secretions, chronic endobronchial infections, and gastrointestinal malabsorption. Knowledge of the epidemiology of infection of patients with cystic fibrosis and effective methods to prevent patient-to-patient transmission have expanded with the use of newer molecular diagnostic methods, resulting in a 2013 update in the Infection Prevention and Control Guideline for Cystic Fibrosis.[9] Fortunately, the population of children with perinatally acquired human immunodeficiency virus (HIV) infection and acquired immunodeficiency syndrome (AIDS) has decreased dramatically since 1994, but new cases of sexually transmitted HIV infection continue to be diagnosed in teens who receive care in children's hospitals. Finally, young infants who have not yet been immunized, or immunosuppressed children who do not respond to vaccines or who lose antibody during disease or treatment (e.g., patients with nephrotic syndrome), have increased susceptibility to vaccine-preventable diseases.

Sources or *Extrinsic* Factors

The source of many HAIs is the endogenous flora of the patient. An asymptomatically colonizing pathogen can invade a patient's bloodstream or be transmitted to other patients on the hands of healthcare personnel (HCP) or on shared equipment. Other important sources of HAIs in infants and children include the mother in the case of neonates, invasive monitoring and supportive equipment, blood products, total parenteral nutrition fluids, lipids, infant formula and human milk, HCP, and other contacts, including adult and sibling visitors. Maternal infection with *Neisseria gonorrhoeae, Treponema pallidum,* HIV, hepatitis B virus, parvovirus B19, *Mycobacterium tuberculosis,* herpes simplex virus, or group B

Streptococcus, or colonization with multidrug-resistant organisms (MDROs), pose substantial threats to the neonate. During perinatal care, procedures such as fetal monitoring using scalp electrodes, fetal transfusion and surgical procedures, umbilical cannulation, and circumcision are potential risk factors for infection. Intrinsically contaminated powdered formulas and infant formulas prepared in contaminated blenders or improperly stored or handled have resulted in sporadic and epidemic infections in the nursery (e.g., *Cronobacter* [formerly *Enterobacter*] *sakazakii*), but such infections have become less frequent since the pathogenesis was defined and contamination reduced.[10] Human milk that has been contaminated by maternal flora or by organisms transmitted through breast pumps has caused isolated serious infections and epidemics. The risks of neonatal hepatitis, cytomegalovirus (CMV) infection, and HIV infection from human milk warrant further caution for handling and use of banked breast milk. With increasing numbers of procedures being performed by pediatric interventional radiologists,[11] an understanding of appropriate aseptic technique, as well as prevention and management of infectious complications, by interventional radiologists is important.[12]

Construction, renovation, demolition, and excavation in and near healthcare facilities are important sources of environmental fungi, (e.g., *Aspergillus* spp., agents of mucormycoses, *Fusarium* spp., *Scedosporium* spp., *Bipolaris* spp.).[13] Immunocompromised patients and patients in the pediatric ICU (PICU) and NICU are at greatest risk for fungal infection, and case fatality rates can be ≥50%, especially if diagnosis and treatment are delayed.

Practices Related to Care of Infants and Young Children.

Several practices must be evaluated with respect to the potentially associated risk of infection. A significant association between reduced levels of nurse staffing and appropriately trained nurses has been demonstrated to increase risk of infection in many studies in both children and adults.[4,14,15] Theoretical concerns exist that infection risk also will increase in association with the innovative practices of co-bedding of twins and kangaroo care in the NICU because of increased opportunity for skin-to-skin exposure of multiple-gestation infants to each other and to their mothers, respectively. Neither the benefits nor the safety of co-bedding multiple-birth infants in the hospital setting has been demonstrated.[16] Overall, the infection risk is reduced with kangaroo care, but transmission of tuberculosis and respiratory syncytial virus (RSV) has occurred in kangaroo mother care units in South Africa.[17] Parents providing kangaroo care should be monitored for the presence of skin infections.

Antimicrobial Selective Pressure.

Exposure to vancomycin and to third-generation cephalosporins contributes substantially to the increase in infections caused by vancomycin-resistant *Enterococcus* (VRE)[18] and multidrug-resistant gram-negative bacilli, including extended spectrum β-lactamase (ESBL)–producing organisms[19] and carbapenem-resistant Enterobacteriaceae[20] (CRE) in children. Additionally, exposure to third-generation cephalosporins also is a risk factor for the development of invasive candidiasis in low birth weight infants in the NICU.[21] Studies of the human microbiome using culture-independent methods have demonstrated the bacterial community diversity on mucosal surfaces and the profound suppressive effect of antimicrobial agents on the population of protective bacteria, *Firmicutes,* thus increasing the risk of colonization and subsequent invasive disease caused by pathogenic bacteria.[22]

Transmission

Routes

The principal modes of transmission of infectious agents are direct and indirect contact, droplet, and airborne.[4]

Contact.

Most infectious agents are transmitted by the contact route on the hands of HCP or through shared items; many pathogens can be transmitted by more than 1 route. Viruses, bacteria, and *Candida* spp. can be transmitted horizontally. Toddlers often share waiting rooms, playrooms, toys, books, and other items and therefore have the potential of transmitting pathogens directly and indirectly to one another. Contaminated bath toys were implicated in an outbreak of multidrug-resistant *Pseudomonas aeruginosa* in a pediatric oncology unit.[23] Although the source of most *Candida* HAIs is the patient's endogenous flora, horizontal transmission, most likely through HCP hands, has been demonstrated in studies using typing by pulsed gel electrophoresis in the NICU and in a pediatric oncology unit.[24,25] Newer molecular diagnostic methods (e.g., whole genome sequencing) are more sensitive and specific than pulsed gel electrophoresis and have proven to be valuable in identifying outbreaks of a variety of pathogens in both pediatric and adult settings.[26,27]

Droplet.

Infectious respiratory droplets >5 μm in diameter are generated from the respiratory tract by coughing, sneezing, or talking or during such procedures as suctioning, intubation, chest physiotherapy, or pulmonary function testing. Transmission of infectious agents by the droplet route requires exposure of mucous membranes to large respiratory droplets within 3 to 6 feet (1 to 2 m) of the infected person. Large respiratory droplets do not remain suspended in the air for prolonged periods, and they settle on environmental surfaces. The dynamics of infectious aerosols can be affected by a variety of factors including characteristics of specific strains of bacteria, temperature, humidity, and number of air exchanges in a room. Adenovirus, influenza virus, and rhinovirus are transmitted primarily by the droplet route, whereas RSV is transmitted primarily by the contact route.[28] Although influenza virus can be transmitted by the airborne route under unusual conditions of reduced air circulation or low absolute humidity, ample evidence indicates that transmission of influenza is prevented by droplet precautions and, in the care of infants, the addition of contact precautions.[29]

Airborne.

Droplet nuclei that arise from desiccation of respiratory droplets and are <5 μm in diameter and contain infectious agents remain suspended in the air for prolonged periods and travel long distances on air currents.[4] Susceptible persons who have not had face-to-face contact or been in the same room as the source person can inhale such infectious particles. *M. tuberculosis,* varicella-zoster virus (VZV), and rubeola virus are the agents most frequently transmitted by the airborne route. Although transmission of *M. tuberculosis* by the airborne route can occur rarely from an infant or young child with active tuberculosis, the more frequent source is the adult visitor with active pulmonary tuberculosis that has not yet been diagnosed; thus screening of visiting family members is an important component for control of tuberculosis in pediatric healthcare facilities.[30]

Some agents (e.g., severe acute respiratory syndrome–coronavirus [SARS-CoV]) can be transmitted as small-particle aerosols under special circumstances of aerosol-generating procedures (e.g., endotracheal intubation, bronchoscopy); therefore, an N95 or higher respirator is indicated for persons in the same airspace when these procedures are performed, but an airborne infection isolation room (AIIR) may not always be required. Roy and Milton[31] proposed the following classification for aerosol transmission when evaluating routes of SARS-CoV transmission:

1. *Obligate:* Under natural conditions, disease occurs following transmission of the agent only through small-particle aerosols (e.g., tuberculosis).

2. *Preferential:* Natural infection results from transmission through multiple routes, but small-particle aerosols are the predominant route (e.g., measles, varicella).

3. *Opportunistic:* Agents naturally cause disease through other routes, but under certain environmental conditions they can be transmitted by fine-particle aerosols.

This conceptual framework can explain rare occurrences of airborne transmission of agents that are transmitted most frequently by other routes (e.g., smallpox, SARS, influenza, noroviruses). Concern about airborne transmission of influenza arose during the 2009 influenza A (H1N1) pandemic. However, the conclusion from all published experiences during the pandemic was that droplet transmission is the usual route of transmission, and surgical masks were noninferior to N95 respirators in preventing laboratory-confirmed influenza in HCP.[32,33] Concerns about unknown or possible routes of transmission of agents that can cause severe disease and have no known treatment often result in more extreme prevention strategies. Therefore, recommended precautions could change as the epidemiology of emerging agents is defined and these controversial issues are resolved. Although no evidence supports airborne transmission of the Ebola virus under usual circumstances in the field, the aerosolization of body fluids that contain high titers of Ebola virus requires additional protection.[34]

Healthcare Personnel

Transmission of microbes between children and HCP is a risk because of the very close contact that occurs during care of infants and young children and is facilitated by overcrowding, understaffing, and too few appropriately trained nurses in pediatric facilities.[4,14] Staffing levels and composition are important components of an effective IPC program. HCP rarely are the *source* of outbreaks of HAIs caused by bacteria and fungi, but when they are, certain factors are usually present that increase the risk of transmission (e.g., sinusitis, draining otitis externa, respiratory tract infections, dermatitis, onychomycosis, wearing of artificial nails).[35–37] Persons with direct patient contact who were wearing artificial nails have been implicated in outbreaks of *P. aeruginosa* and ESBL-producing *Klebsiella pneumoniae* in NICUs; therefore, the use of artificial nails or extenders is prohibited in persons who have direct contact with high-risk patients.[4] Several published studies have shown that infected pediatric HCP, including resident physicians, transmitted *Bordetella pertussis* to other patients and can be the source of other vaccine-preventable infections in healthcare.[38,39]

Pathogens

Although no agreed-on definition for what constitutes an “epidemiologically important organism” has yet been established, the following characteristics apply and are presented for guidance to infection control staff in the 2007 HICPAC Guideline for Isolation Precautions in Healthcare Settings[4]:

1. A propensity for transmission within healthcare facilities based

on published reports and the occurrence of temporal or geographic clusters of infection in >2 patients (e.g., VRE, methicillin-resistant *Staphylococcus aureus* [MRSA], and methicillin-susceptible *S. aureus* [MSSA], *Clostridium difficile,* norovirus, RSV, influenza, rotavirus, *Enterobacter* spp., *Serratia* spp., group A *Streptococcus*). A single case of healthcare-associated invasive disease caused by certain pathogens (e.g., group A *Streptococcus* postoperatively or in burn units; *Legionella* sp.; *Aspergillus* sp.) should trigger an investigation.

2. Association with antimicrobial resistance (e.g., MRSA, VRE, ESBL-producing gram-negative bacilli (GNB), CRE, *Burkholderia cepacia, Ralstonia* spp., *Stenotrophomonas maltophilia,* and *Acinetobacter* spp.). Infections caused by intrinsically resistant GNB also suggest possible contamination of water or medication.

3. Association with serious clinical disease and increased morbidity and mortality (e.g., MRSA and MSSA, group A *Streptococcus*).

4. A newly discovered or reemerging pathogen (e.g., vancomycin-intermediate or vancomycin-resistant *S. aureus* [VISA, VRSA], *C. difficile*).

Pathogens associated with HAIs in children differ from those in adults in that respiratory viruses are more frequently associated with transmission in pediatric healthcare facilities. Respiratory viruses (e.g., RSV, parainfluenza, adenovirus, human metapneumovirus) have been implicated in outbreaks in high-risk units. As more respiratory viruses and gastrointestinal pathogens are identified by using highly sensitive molecular methods, epidemiologic studies will be required to define further the risk of transmission in healthcare facilities and the clinical significance of positive antigen detection test results.[40,41] Healthcare-associated outbreaks of varicella, measles, and rotavirus infection now are rare events because of the consistent use of vaccines by children and HCP.

The emergence of community-associated MRSA isolates characterized by the unique scc *mec* type IV element was first observed among infants and children. As rates of colonization with community-associated MRSA at the time of hospital admission increased, so did transmission of community strains, most often

USA 300, within the hospital and especially within the NICU, thus making prevention especially challenging. Other MDROs (e.g., VRE, ESBLs, and CRE, especially *K. pneumoniae*) have emerged as the most challenging healthcare-associated pathogens in both pediatric and adult settings, and otherwise healthy children in the community can be colonized asymptomatically with these MDROs.[42] GNB, including ESBL and other multidrug-resistant isolates, are more frequent than MRSA and VRE in many PICUs and NICUs. Patients who are transferred from chronic care facilities may be colonized with MDR GNB at the time of admission to the PICU. Trends in targeted MDROs are tracked in the National Nosocomial Infections Surveillance system (NNIS), now NHSN ICUs. HAIs caused by MDROs are associated with increased length of stay, increased morbidity and mortality, and increased cost, in part because of the delay in initiating effective antimicrobial therapy.[43,44] Although the prevalence of specific MDROs is lower in pediatric institutions, the same principles of target identification and interventions to control MDROs apply in all settings.

C. difficile is an important pathogen in children, as it is in adults, especially in children receiving chemotherapy. Testing for *C. difficile* in the first year of life is not advised because of the high asymptomatic colonization rate with toxigenic strains in this age group.

Candida spp. are the third most frequent pathogens associated with bloodstream infections in US NICUs. There is considerable center-to-center variability in both the incidence of invasive candidiasis and the proportion of *Candida* infections caused by *Candida* non-*albicans* spp., most of which are resistant to fluconazole. Risk factors for *Candida* infections include prolonged length of stay in an ICU, use of central venous catheters, intralipids, histamine (H_2)-blocking agents, and exposure to third-generation cephalosporins. GNB and *Candida* spp. are especially important pathogens for HAIs in patients with intestinal failure who are receiving total parenteral nutrition, and these organisms can cause repeated episodes of sepsis. The incidence of *Candida* infections had increased in incidence in most PICUs and NICUs during the 1990s, but the rate of *C. albicans* and non-*albicans* central line–associated bloodstream infections decreased by 75% in all birth weight categories from 1999 to 2009,[45] likely a result of improved infection control practices, antimicrobial stewardship, and use of fluconazole prophylaxis in the very low birth weight preterm infants. The most recently published clinical practice guidelines of the Infectious Diseases Society of America (IDSA) recommend the use of oral or intravenous fluconazole prophylaxis in infants weighing <1000 g at birth in NICUs with high rates (>10%) of invasive candidiasis, based on high quality of evidence to support efficacy and safety.[46] Additionally, empiric antifungal therapy in preterm infants of ≤1000 g birth weight is associated with improved survival rates without adverse outcomes.[47] The staff members of each NICU first must optimize infection control practices and then assess the remaining risk of *Candida* infections. Finally, environmental fungi (e.g., *Aspergillus, Fusarium, Scedosporium, Bipolaris,* agents of mucormycosis) are important sources of infection for severely immunocompromised patients; meticulous attention to the conditions of the internal environment of any facility that provides care for severely immunocompromised patients is required, as well as prevention of possible exposure to construction dust in and around healthcare facilities.[13] With the advent of more effective and less toxic antifungal agents and improved outcomes, it is important to identify promptly the infecting agent by obtaining tissue samples and to determine susceptibility to candidate antifungal agents.

Prevention Programs

Prevention remains the mainstay of infection control and requires special considerations in children. The goals of IPC are to prevent the transmission of infectious agents among individual patients or groups of patients, visitors, and HCP who care for them. As new pathogens emerge, new strategies for prevention emerge. The experience treating EVD in the US in 2014 and 2015 is the most recent example of changes in the usual infection prevention paradigm that were required, with a renewed emphasis on the 3 tiers of the hierarchy of controls (e.g., engineering, administration, and PPE), donning and doffing of PPE, and use of trained observers.[6,7] If prevention cannot always be achieved, the strategy of early diagnosis, treatment, and containment is critical.

A series of IPC guidelines have been developed and updated at varying intervals by the HICPAC/CDC, IDSA, Society for

Healthcare Epidemiology of America (SHEA), American Academy of Pediatrics, Association for Professionals in Infection Control and Epidemiology, and others to provide evidence-based and rated recommendations for practices that are associated with reduced rates of HAIs, especially those infections associated with the use of medical devices and surgical procedures. Recommended isolation precautions by infectious agent also can be found in the most recent edition of the *Red Book Report of the Committee on Infectious Diseases* of the American Academy of Pediatrics.

Prevention *bundles* are groups of 3 to 5 evidence-based "best practices" with respect to a process that individually improve care, but when applied together result in substantially greater reduction in infection rates. Adherence to the individual measures within a bundle is readily measured. Bundled practices are used most frequently for prevention of device- or procedure-related HAIs, but they can be applied to prevention of any type of HAI.

Administrative Factors

The importance of certain administrative measures for a successful IPC program has been demonstrated. A white paper published by SHEA summarizes the necessary infrastructure for an effective IPC program in modern times. The paper addresses the expansion of IPC responsibilities from a relatively narrow focus on acute infectious disease events in the acute care hospital, surveillance, and implementation of recommended isolation precautions to a broader set of activities across the continuum of care requiring team work within and beyond individual facilities, usually including large networks.[48] Because IPC comprises one component of the institutional culture of safety, it is critical to obtain support from the senior leadership of healthcare organizations to provide necessary fiscal and human resources for a proactive, successful IPC program. Critical elements requiring administrative support include access to the following: (1) appropriately trained healthcare epidemiologists and IPC personnel; (2) clinical microbiology laboratory services needed to support infection control outbreak investigations, including ability to perform molecular diagnostic testing; (3) data-mining programs and information technology specialists; (4) multidisciplinary programs to ensure judicious use of antimicrobial agents and control of resistance; (5) development of effective educational information for delivery to HCP, patients, families, and visitors; and (6) local and state health department resources for preparedness. Provision of adequate numbers of well-trained infection preventionists and bedside nursing staff is critical for success.

Infection Prevention and Control Team

An effective IPC program improves safety of patients and HCP and decreases short-term and long-term morbidity, mortality, and healthcare costs.[49] The IPC committee of a facility establishes policies and procedures to prevent or reduce the incidence and costs associated with HAIs. This committee should be one of the strongest and most accessible committees in the facility; committee composition should be considered carefully and limited to active, authoritative participants who have well-defined committee responsibilities and who represent major groups within the hospital. The chairperson should be a good communicator with expertise in IPC issues, healthcare epidemiology, and clinical pediatric infectious diseases. Important functions of the IPC committee are regular review of IPC policies and development of new policies as needed. Annual review of all policies is required by The Joint Commission and can be accomplished optimally by careful review of a few policies each month. With the advent of unannounced inspections, a constant state of readiness is required.

The hospital epidemiologist or medical director of the pediatric IPC department usually is a physician with training in pediatric infectious diseases and dedicated expertise in healthcare epidemiology. In multispecialty medical centers where infants and children comprise a small proportion of patients, pediatric infectious disease experts should be consulted for management of pediatric IPC issues and report to the broader IPC leadership. The skillsets, training, and competencies needed for success as a healthcare epidemiologist were summarized in another white paper published by the SHEA.[50] Certification for healthcare epidemiologists has not yet been developed.

Infection preventionists are specialized professionals with advanced training, and preferably certification, in IPC. Although most infection preventionists are registered nurses, other professionals, including microbiologists, medical technologists, pharmacists, and epidemiologists, are successful in this position. Pediatric patients should have infection preventionist services provided by professionals with expertise and training in the care of children. In a large, general hospital, at least 1 infection preventionist should be dedicated to IPC services for children. The responsibilities of infection preventionists have expanded greatly and include the following:

1. Surveillance and IPC in facilities affiliated with primary acute care hospitals (e.g., ambulatory clinics, day-surgery centers, long-term care facilities, rehabilitation centers, home care) in addition to the primary hospital

2. Oversight of occupational health services related to IPC (e.g., assessment of risk and administration of recommended prophylaxis following exposure to infectious agents, tuberculosis screening, influenza and pertussis vaccination, respiratory protection fit testing, administration of other vaccines as indicated during infectious disease crises such as preexposure smallpox vaccine in 2003 and pandemic influenza A [H1N1] vaccine in 2009)

3. Preparedness planning for annual influenza outbreaks, pandemic influenza, SARS, Middle East respiratory syndrome (MERS), bioweapons attacks, and EVD

4. Adherence monitoring for selected IPC practices

5. Oversight of risk assessment and implementation of preventive measures associated with construction, renovation, and other environmental conditions associated with increased infection risk

6. Participation in antimicrobial stewardship programs, focusing on prevention of transmission of MDROs

7. Evaluation of new products and medical devices that could be associated with increased infection risk (e.g., endoscopes,[51] contaminated injectable medications[52]) and introduction and assessment of performance after implementation of modified

products

8. Mandatory public reporting of HAI rates in states according to enacted legislation

9. Increased communication with the public and with local public health departments concerning infection control–related issues

10. Participation in local and multicenter reporting and research projects

IPC programs must be adequately staffed to perform all the foregoing activities. Thus the ratio of 1 infection preventionist to 250 beds that was associated with a 30% reduction in the rates of nosocomial infection in the Study on Efficacy of Nosocomial Infection Control (SENIC) performed in the 1970s no longer is sufficient because the complexity of patient populations and responsibilities have increased. Many experts recommend that a ratio of 1 infection preventionist to 100 beds is more appropriate for the current workload, but no study has been performed to confirm the effectiveness of that ratio. No information is available on the number of IPC personnel required outside acute care, but it is clear that persons well trained in IPC must be available for all sites where healthcare is delivered. Data collected from a member workforce survey conducted in 2015 by the Association for Professionals in Infection Control and Epidemiology are expected to help determine the optimal number of infection preventionists for different healthcare settings based on the current responsibilities and demographics of infection preventionists.

Surveillance

Facilitywide or Systemwide Surveillance

Surveillance for HAIs consists of a systematic method of determining the incidence and distribution of infections acquired by hospitalized patients. The CDC recommends the following: (1) prospective surveillance on a regular basis by trained infection preventionists, using standardized definitions; (2) analysis of infection rates using established epidemiologic and statistical methods (e.g., calculation of rates using appropriate denominators that reflect duration of exposure; use of statistical process control charts for trending rates); (3) regular use of data in decision making; and (4) employment of an effective and trained healthcare epidemiologist who develops IPC strategies and policies and serves as a liaison with the medical community and administration.[53–55] The CDC has established a set of standard definitions of HAIs that have been validated and accepted widely with updates posted on the CDC NHSN website. Standardization of surveillance methodology has become especially important with the advent of state legislation for mandatory reporting of HAI rates to the public. The NHSN now receives, analyzes, and reports data from >17,000 healthcare facilities in the US. A standardized infection ratio (SIR) that takes into account differences in risk among healthcare settings, unit types, procedures, and patient populations has been included in summary reports of HAI rates since 2009.[56] The Centers for Medicare and Medicaid Services and most states use the NHSN data for public reporting of HAI rates on their websites. Although much effort has been directed toward making these data understandable and useful to consumers, interpretation of these data by the public remains difficult, and more research is needed to optimize methods of data display to the public.[57] New York State is the first state to have published an improvement in process and outcomes of central line–associated bloodstream infection rates in NICUs following implementation of a public reporting program.[58]

Although various surveillance methods are used, the basic goals and elements are similar and include using standardized definitions of infection, finding and collecting cases of HAIs, tabulating data, using appropriate denominators that reflect duration of risk, analyzing and interpreting the data, reporting important deviations from endemic rates (epidemic, outbreaks) to the bedside care providers and to the facility administrators, implementing appropriate control measures, auditing adherence rates for recommended processes, and assessing efficacy of the control measures. Medical centers can use different methods of surveillance, as outlined in Box 2.1. Most experts agree that a combination of methods enhances surveillance and reliability of data, and some combination of clinical chart review and database retrieval is important. Whatever data collection systems are used, validation is required. Administrative databases created for the purposes of billing should not be used as the sole source to identify HAIs because of overestimates and underestimates that result from inaccurate coding of HAIs.[59] Use of software designed specifically for IPC data entry and analysis facilitates real-time tracking of trends and timely intervention when clusters are identified. The IPC team should participate in the development and update of electronic medical record systems for a healthcare organization, to ensure that surveillance needs will be met.

Box 2.1

Sources of Data for Surveillance

Clinical rounds with physicians or nurses, or both

Review of:

- Patients' orders
- Radiology reports and databases
- Pharmacy reports and databases
- Operating room diagnoses and procedures
- Microbiology: bacteriology, virology, mycology, mycobacteriology, serology reports, autopsy reports, data-mining reports

Postdischarge surveillance, especially for surgical site infections

Public health surveillance

Review of:

- Employee health reports
- Admission diagnoses

- Outpatient diagnoses
- Administrative databases, but these should not be used as a sole source because of inaccurate coding of healthcare-associated infections

Targeted Pathogen-Specific Active Surveillance Cultures

Controversy has surrounded the role of obtaining active surveillance cultures from all patients admitted to an acute care hospital, especially to an ICU, to detect asymptomatic colonization with MRSA or VRE and then placing those persons on Contact Precautions in an endemic setting, a practice referred to as a *vertical* approach.[60,61] More recently published experiences demonstrate the benefits of a *horizontal* approach to reduce the risk of transmission of a broader variety of pathogens,[61] and a framework for a less restrictive approach has been published.[62] Contributing factors to the benefits of the horizontal approach include the following: (1) widespread implementation of bundled prevention practices, including limiting use of unnecessary medical devices; (2) improved understanding and more consistent implementation of Standard Precautions, especially hand hygiene; (3) establishment of the safety and efficacy of universal decolonization using chlorhexidine bathing in ICUs[63,64] and NICUs for infants weighing >1000 g at birth[65]; (4) improving environmental cleaning; and (5) promoting antimicrobial stewardship. A program of active surveillance cultures and Contact Precautions is best reserved for implementation in a targeted fashion (i.e., in units with an indication of ongoing transmission of MRSA, VRE, or other MDROs) according to 2006 guidelines, if transmission continues after standardized horizontal interventions have been completely implemented.[5] At this time, no formal recommendation has been made to discontinue routine use of Contact Precautions for patients with asymptomatic colonization with MRSA or VRE in an endemic setting; thus each IPC program must determine practice based on local conditions and follow with close auditing and surveillance for potential adverse outcomes.

The microbiology laboratory can provide online culture information about individual patients, outbreaks of infection, antibiograms (antibiotic susceptibility patterns of pathogens summarized periodically), and employee infection data. The laboratory also can assist with surveillance cultures and facilitation of molecular typing of isolates during outbreak investigations. Rapid diagnostic testing of clinical specimens for identification of respiratory and gastrointestinal tract viruses and *B. pertussis* is especially important for pediatric facilities. The IPC division and the microbiology laboratory must communicate daily because even *requests* for cultures or other diagnostic testing from physicians (e.g., *M. tuberculosis, Neisseria meningitidis, C. difficile*) can identify patients early who are infected, are at high risk of infection, or require isolation. If microbiology laboratory work is outsourced, it is important to ensure that the services needed to support effective ICP be available, as delineated in a 2013 guideline developed by the IDSA and the American Society for Microbiology.[66]

Control of unusual infections or outbreaks in the community generally is the responsibility of the local or state public health department; however, the individual facility must be responsible for preventing transmission within that facility. Public health agencies can be helpful, particularly in alerting hospitals of community outbreaks so that outpatient and inpatient diagnosis, treatment, necessary isolation, and other preventive measures are implemented promptly to avoid further spread. Conversely, designated persons in the hospital must notify public health department personnel of reportable infections to facilitate early diagnosis, treatment, and infection control in the community. Benefits of community or regional collaboratives of individual healthcare facilities and local public health departments for prevention of HAIs, especially those caused by MDROs, have been demonstrated, and this collaboration should be encouraged.[4,67]

Antimicrobial Stewardship

The rapid increase of MDROs is a public health threat. Between 20% and 50% of antibiotics prescribed in US hospitals are either inappropriate or unnecessary.[68] In 2014, the President's Council of Advisors on Science and Technology submitted a 78-page *Report to* *the President on Combating Antibiotic Resistance* that raised awareness of antimicrobial resistance to a national level.[69] A National Action Plan based on this report was released in March 2015, and funding was made available for its implementation.

Antimicrobial stewardship was defined in a consensus statement by the IDSA, SHEA, and Pediatric Infectious Diseases Society in 2012 as "coordinated interventions designed to improve and measure the appropriate use of antibiotic agents by promoting the selection of the optimal antibiotic regimen, including dosing, duration and route of administration."[70] Antimicrobial stewardship programs are collaborative partnerships among infection preventionists, healthcare epidemiologists, clinical pharmacists, and microbiologists. Hospital administrative support for the infrastructure required for ongoing measurement and reporting of antimicrobial use and other related outcome measures, including feedback to prescribers, is a critical component of a successful antimicrobial stewardship program. An antimicrobial stewardship program can optimize clinical outcomes while decreasing unintended consequences of antimicrobial use, including the emergence of resistant organisms. Additionally, use of specific antimicrobial agents can alert the IPC program to the presence of potentially infectious patients (e.g., with pulmonary tuberculosis, MDROs). National guidelines exist for developing and implementing an institutional antimicrobial stewardship program, including core components for acute care hospitals and for long-term care facilities.[68,70] The Natinal Quality Forum and its partners have also developed a Playbook that provides additional guidance for implementation of antimicrobial stewardship programs in acute care. The knowledge and skills required for antimicrobial stewardship leaders also have been defined.[50,71]

The effectiveness of antimicrobial stewardship programs in achieving improved patient outcomes is evident in pediatric acute care hospitals,[72,73] including the NICU,[74,75] in ambulatory settings, and in long-term care facilities. The area of antimicrobial stewardship, however, requires additional research to establish optimal methods in various pediatric specialty populations. One practice from the CDC GET SMART program that can be implemented by each prescriber in most settings is the antibiotic "time out" that consists of reviewing patient data at 48 to 72 hours of treatment to determine which of the following is indicated: (1) continue antibiotic treatment; (2) change to a narrower-spectrum agent; (3) change from a parenteral to an oral agent; or (4) shorten or conclude therapy.[68]

Isolation Precautions

Isolation of patients with potentially transmissible infectious diseases is a strategy proven to prevent transmission of infectious agents in healthcare settings. Many published studies, performed in both adult and pediatric settings, provide a strong evidence base for most recommendations for isolation precautions and for limiting outbreaks. However, controversies exist concerning the most clinically and cost-effective measures for preventing certain HAIs, especially those associated with MDROs. As discussed earlier in the section on surveillance, a call has gone out to reconsider recommendations for isolation of patients who are asymptomatically colonized with MRSA or VRE, but no definite recommendation has been made by the HICPAC/CDC, SHEA, or Association for Professionals in Infection Control and Epidemiology.

Since 1970, the guidelines for isolation developed by CDC have responded to the needs of the evolving US healthcare systems. For example, universal precautions became a required standard in response to the HIV epidemic that emerged in the 1980s and the need to prevent acquisition of bloodborne pathogens (e.g., HIV, hepatitis B and C viruses) by HCP through skin, eye, mucous membrane, or parenteral contact with blood or other potentially infectious materials from persons not known to be or suspected of being infected. Universal precautions were modified and have been known as Standard Precautions since publication of the 1996 Guideline for Isolation. The federal Needlestick Safety and Prevention Act, signed into law in November 2000, authorized the Occupational Safety and Health Administration's revision of its Bloodborne Pathogens Standard more explicitly to require the use of safety-engineered sharp devices.[76]

Evidence and recommendations are provided for the prevention of transmission of MDROs such as MRSA, VRE, VISA, VRSA, and GNB.[4,5] The components of a protective environment for prevention of environmental fungal infections in HSCT recipients are summarized.[4] Finally, evidence-based, rated recommendations for administrative measures that are necessary for effective prevention of infection in healthcare settings are provided.

Standard Precautions

The most recent Guideline for Isolation Precautions published in 2007[4] reaffirms *Standard Precautions*, a combination of universal precautions and body substance isolation, as the foundation of transmission prevention measures. Critical thinking is required for HCP to recognize the importance of body fluids, excretions, and secretions in the transmission of infectious pathogens and take appropriate protective precautions by using PPE (e.g., masks, gowns, gloves, face shields, or goggles) and safety devices when exposure is likely even if an infection is not suspected or known. In addition, these updated guidelines provide recommendations for Standard Precautions in all settings in which healthcare is delivered (acute care hospitals, ambulatory surgical and medical centers, long-term care facilities, and home health agencies). The components of Standard Precautions are summarized in Table 2.1. In the most recent HICPAC/CDC isolation guideline,[4] safe injection practices are included as a component of Standard Precautions. Despite the emphasis on safe injection practices, transmission of hepatitis B and C viruses continues to be reported in ambulatory care settings as a result of failure to follow recommended practices, thus indicating a need to reiterate the established effective practices.[77] During 2008 to 2014, 45 outbreaks (≥2 cases) of viral hepatitis related to healthcare were reported to the CDC; of these, 42 (95%) occurred in nonhospital settings. A review of clusters of transmission of hepatitis C virus in dialysis centers from 2005 to 2015 identified the following potential infection control breaches: (1) use of multidose vials for heparin or saline administration; (2) poor compliance with hand hygiene before and after patient contacts or after touching a possibly contaminated surface; (3) failure to change gloves between patient contacts or after contact with a potentially contaminated surface; (4) failure to disinfect environmental surfaces adequately; (5) unsafe injection practices; (6) failure to disinfect shared equipment between patient uses; (7)

lack of a separate area for medication preparation; and (8) failure to have clean and dirty utility rooms clearly separated.[78]

TABLE 2.1

Recommendations for Application of Standard Precautions for the Care of All Patients in All Healthcare Settings

Component	Recommendations for Performance
Hand hygiene	Perform before touching patients and before donning gloves; after touching blood, body fluids, secretions, excretions, contaminated items; immediately after removing gloves; between patient contacts. Alcohol-containing antiseptic hand rubs preferred except when hands are visibly soiled with blood or other proteinaceous materials or if exposure to spores (e.g., *Clostridium difficile, Bacillus anthracis*) is likely to have occurred
Gloves	Use for touching blood, body fluids, secretions, excretions, contaminated items; for touching mucous membranes and nonintact skin
Gown	Wear during procedures and patient care activities when contact of clothing or exposed skin with blood or body fluids, secretions, and excretions is anticipated
Mask,[a] eye protection (goggles), face shield	Wear during procedures and patient care activities likely to generate splashes or sprays of blood, body fluids, secretions (especially suctioning, endotracheal intubation) to protect healthcare personnel. For patient protection, the person inserting an epidural anesthesia needle or performing myelograms should use a mask when prolonged exposure of the puncture site is likely to occur
Soiled patient-care equipment	Handle in a manner that prevents transfer of microorganisms to others and to the environment; wear gloves if equipment is visibly contaminated; perform hand hygiene
Environmental control	Develop procedures for routine care, cleaning, and disinfection of environmental surfaces, especially frequently touched surfaces in patient care areas
Textiles and laundry	Handle in a manner that prevents transfer of microorganisms to others and to the environment
Safe injection practices (use of needles and other sharps)	Do not recap, bend, break, or hand-manipulate used needles; if recapping is required, use a one-handed scoop technique only; use needle-free safety devices when available; place used sharps in a puncture-resistant container. Use a sterile, single-use, disposable needle and syringe for each injection given. Single-dose medication vials are preferred when medications are administered to >1 patient
Patient resuscitation	Use a mouthpiece, resuscitation bag, or other ventilation device to prevent contact with mouth and oral secretions
Patient placement	Prioritize for a single-patient room if the patient is at increased risk of transmission, is likely to contaminate the environment, does not maintain appropriate hygiene, or is at increased risk of acquiring infection or developing adverse outcome following infection
Respiratory hygiene and cough etiquette[b]	Instruct symptomatic persons to cover the mouth or nose when sneezing or coughing; use tissues and dispose in no-touch receptacle; observe hand hygiene after soiling of hands with respiratory secretions; wear a surgical mask if tolerated or maintain spatial separation, >1–2 m (3–6 feet) if possible

[a] During aerosol-generating procedures on patients with suspected or proven infections transmitted by aerosols (e.g., severe acute respiratory syndrome), wear a fit-tested N95 or higher respirator in addition to gloves, gown, and face and eye protection.

[b] Source containment of infectious respiratory secretions in symptomatic patients, beginning at the initial point of encounter (e.g., triage and reception areas in emergency departments and physician offices).

Modified with permission from Siegel JD, Rhinehart E, Jackson M, et al. Guideline for isolation precautions: preventing transmission of infectious agents in healthcare settings, 2007. Am J Infect Control 2007;35(Suppl 2):S65–S164.

Two additions were made to Standard Precautions in 2007: (1) *respiratory hygiene or cough etiquette* for source containment by people with signs and symptoms of respiratory tract infection and (2) *use of a mask* by personnel inserting an epidural anesthesia needle or performing a myelogram when prolonged exposure of the puncture site is likely. Both components have a strong evidence base.

Implementation of Standard Precautions requires the availability of PPE in proximity to all patient care areas. HCP with exudative lesions or weeping dermatitis must avoid direct patient care and handling of patient care equipment. Persons having direct patient contact should be able to anticipate exposure incurring risks and steps to take if a high-risk exposure occurs. Exposures of concern are as follows: exposures to blood or other potentially infectious material defined as an injury with a contaminated sharp object (e.g., needlestick, scalpel cut); a spill or splash of blood or other potentially infectious material onto nonintact skin (e.g., cuts, hangnails, dermatitis, abrasions, chapped skin) or onto a mucous membrane (e.g., mouth, nose, eye); or blood exposure covering a large area of normal skin. Patient-related duties that do *not* constitute high-risk exposures include handling food trays or furniture, pushing wheelchairs or stretchers, using restrooms or telephones, having personal contact with patients (e.g., giving information, touching intact skin, bathing, giving a back rub, shaking hands), or performing clerical or administrative functions for a patient.

If hands or other skin surfaces are exposed to blood or other potentially infectious material, the area should be washed immediately with soap and water for at least 10 seconds and rinsed with running water for at least 10 seconds. For an eye, nose, or mouth splash with blood or body fluids, the area should be irrigated immediately with a large volume of water. If a skin cut, puncture, or lesion is exposed to blood or other potentially infectious material, the area should be washed immediately with soap and water for at least 10 seconds and rinsed with 70% isopropyl alcohol. Any exposure incident should be reported immediately to the occupational health department to determine whether blood samples are required from the source patient and the exposed person and if immediate prophylaxis is indicated.

All HCP should know where to find the exposure control plan specific to each place of employment, whom to contact, where to go, and what to do if inadvertently exposed to blood or body fluids. Important resources include the occupational health department, the emergency department, and the infection control or hospital epidemiology division. The most important recommendation in any accidental exposure is to seek advice and intervention immediately because the efficacy of recommended prophylactic regimens is improved with shorter intervals after exposure, such as for hepatitis B immune globulin administration after exposure to hepatitis B virus or for antiretroviral therapy after percutaneous exposure to HIV. Chemoprophylaxis following exposure to HIV-infected material is most effective if it is initiated as soon as possible, but within hours of exposure.[79] The current guidelines recommend using ≥3 drugs for postexposure prophylaxis of HIV independent of the severity of exposure. Updates are posted on the CDC website as they are developed. Reporting a work-related exposure is required for subsequent medical care and workers' compensation.

Transmission-Based Precautions

Transmission-Based Precautions are designed for patients with documented or suspected infection with pathogens for which additional precautions beyond Standard Precautions are needed to prevent transmission. The 3 categories of Transmission-Based Precautions are *Contact Precautions, Droplet Precautions,* and *Airborne Precautions,* and they are based on the likely routes of transmission of specific infectious agents. Transmission-based precautions are combined for infectious agents that have more than 1 route of transmission. When used singly or in combination, such precautions always are used in addition to Standard Precautions. Transmission-based precautions applied at the time of initial contact, based on the clinical presentation and the most likely pathogens are referred to as *Empiric Precautions* or *Syndromic*

Precautions. This approach is useful especially for emerging agents (e.g., SARS-CoV, avian influenza, pandemic influenza), for which information concerning routes of transmission is evolving. The categories of clinical presentation are as follows: diarrhea, central nervous system, generalized rash or exanthem, respiratory, skin or wound infection. Single-patient rooms always are preferred for children needing Transmission-Based Precautions. If single-patient rooms are unavailable, cohorting of patients, and preferably of staff, according to clinical diagnosis is recommended. The experience of treating EVD in the US in 2014 led to the development of special precautions after viral transmission to 2 nurses occurred as a result of patients' extraordinarily high viral loads and large volumes of emitted body fluids.[6] PPE for all transmission-based precautions is donned *upon entry* into the room to protect against acquisition of pathogens from contaminated surfaces, even if direct contact with the patient is not intended.

Although targeted Contact Precautions and universal gowning and gloving are effective for preventing transmission of infectious agents, potential adverse effects in patients placed on Contact Precautions have been described (e.g., depression, fewer visits from the healthcare team, increased rates of hypoglycemia or hyperglycemia, increased falls).[80] Additionally, adherence to Contact Precautions decreases as the number of patients on Contact Precautions increases.[81] Finally, a simulation study demonstrated contamination of HCP skin and clothing during doffing of gowns and gloves[82]; this study effectively demonstrated the PPE lessons learned during the SARS and EVD experiences. Evidence supports the importance of applying Contact Precautions only when indicated, obtaining training on the use of PPE, having effective PPE readily available, and practicing consistent and precise use of PPE.[83]

Table 2.2 lists the 3 categories of isolation based on routes of transmission and their necessary components. Table 2.3 lists precautions by syndromes, to be used when a patient has an infectious disease and the agent is not yet identified. For infectious agents that are more likely to be transmitted by the droplet route (e.g., pandemic influenza), droplet precautions (with use of surgical mask) are appropriate; however, during an aerosol-generating procedure, N95 or higher respirators are indicated.[84]

TABLE 2.2

Transmission-Based Precautions[a]

Component	Contact	Droplet	Airborne
Hand hygiene	Per Standard Precautions Perform 5 moments of hand hygiene, and ***upon entry*** into room Soap and water preferred over alcohol hand rub for *Clostridium difficile, Bacillus anthracis* spores	Per Standard Precautions Perform 5 moments of hand hygiene, and ***upon entry*** into room	Per Standard Precautions Perform 5 moments of hand hygiene, and ***upon entry*** into room
Gown	Yes; don before or ***upon entry*** into room	Per Standard Precautions Add to droplet precautions for infants, young children, or presence of diarrhea	Per Standard Precautions and, if infectious, draining skin lesions present
Gloves	Yes; don before or ***upon entry*** into room	Per Standard Precautions. Add for infants, young children and/or presence of diarrhea	Per Standard Precautions Add for infants, young children or presence of diarrhea
Mask	Per Standard Precautions	Yes; don before or ***upon entry*** into room	Don N95 particulate respirator or higher ***before entry*** into room
Goggles or face shield	Per Standard Precautions	Per Standard Precautions Always for SARS, avian influenza	Per Standard Precautions Always for SARS, avian influenza
N95 or higher respirator (Always don *before entry* into room)	When aerosol-generating procedures performed for influenza, SARS, VHF[b]	When aerosol-generating procedures performed for influenza, SARS, VHF	Yes; don ***before entry*** into room
Room placement	Single-patient room preferred Cohort similar infections if single-patient rooms unavailable	Single-patient room preferred Cohort similar infections if single-patient rooms unavailable	Single-patient room Negative air pressure; 12 air changes/hr for new construction, 6 air changes/hr for existing rooms
Environmental measures	Increased frequency, especially in the presence of diarrhea, transmission of *C. difficile*, norovirus Bleach for VRE, *C. difficile*, norovirus	Routine	Routine
Transport	Mask patient if coughing Cover infectious skin lesions PPE not routinely required for transporter	Mask patient	Mask patient Cover infectious skin lesions

[a] In addition to Standard precautions, use Transmission-Based Precautions for patients with highly transmissible or epidemiologically important pathogens for which additional precautions are needed.

[b] Includes Ebola virus. Consult most recent Centers for Disease Control and Prevention and World Health Organization guidelines for recommended infection control precautions for Ebola virus disease.

PPE, personal protective equipment; SARS, severe acute respiratory syndrome; VHF, viral hemorrhagic fever; VRE, vancomycin-resistant *Enterococcus*.

Modified with permission from Siegel JD, Rhinehart E, Jackson M, et al. Guideline for isolation precautions: preventing transmission of infectious agents in healthcare settings, 2007. Am J Infect Control 2007;35(Suppl 2):S65–S164.

TABLE 2.3

Clinical Syndromes or Conditions Warranting Empiric Transmission-Based Precautions in Addition to Standard Precautions Pending Confirmation of Diagnosis[a]

Clinical Syndrome or Condition[b]	Potential Pathogens[c]	Empiric Precautions (Always Includes Standard Precautions)
DIARRHEA		
Acute diarrhea with a likely infectious cause in an incontinent or diapered patient	Enteric pathogens[d]	Contact Precautions (pediatrics and adult)
MENINGITIS	*Neisseria meningitidis*	Droplet Precautions for first 24 hr of antimicrobial therapy; mask, face, and eye protection for intubation
	Enteroviruses	Contact Precautions for infants and children
	Mycobacterium tuberculosis	Airborne Precautions if pulmonary infiltrate
		Airborne Precautions plus Contact Precautions if potentially infectious draining body fluid present
RASH OR EXANTHEMS, GENERALIZED, ORIGIN UNKNOWN		
Petechial or ecchymotic exanthem with fever (general)	*N. meningitidis*	Droplet Precautions for first 24 hr of antimicrobial therapy
If traveled in an area with an ongoing outbreak of viral hemorrhagic fever in the 10 days before onset of fever	Ebola, Lassa, Marburg viruses	Airborne Precautions plus Contact Precautions, with face and eye protection, emphasizing safety sharps and barrier precautions when blood exposure likely In the United States, asymptomatic persons can be managed in Ebola assessment centers. Transfer symptomatic persons with infection to biocontainment units Use a single-use fluid-resistant or impermeable gown that extends to at least midcalf or a coverall without an integrated hood. Two pairs of gloves should be worn. Use a single-use fluid-resistant or impermeable boot cover. A single-use fluid resistant or impermeable apron

		should be worn to cover the torso if the patient has vomiting or diarrhea Consult CDC, WHO websites for current recommendations
Vesicular	Varicella-zoster, herpes simplex, variola (smallpox), vaccinia viruses	Airborne plus Contact Precautions Contact Precautions only if herpes simplex, localized zoster in an immunocompetent host, or vaccinia viruses most likely
Maculopapular with cough, coryza, and fever	Rubeola (measles) virus	Airborne Precautions
RESPIRATORY INFECTIONS		
Cough, fever, or upper-lobe pulmonary infiltrate in an HIV-negative patient or a patient at low risk for HIV infection	*M. tuberculosis,* respiratory viruses, *Streptococcus pneumoniae, Staphylococcus aureus* (MSSA or MRSA)	Airborne Precautions plus Contact Precautions until *M. tuberculosis* ruled out Droplet Precautions if respiratory viruses most likely
Cough, fever, or pulmonary infiltrate in any lung location in an HIV-infected patient or a patient at high risk for HIV infection	*M. tuberculosis,* respiratory viruses, *Streptococcus pneumoniae, Staphylococcus aureus* (MSSA or MRSA)	Airborne Precautions plus Contact Precautions Use eye and face protection if aerosol-generating procedure performed or contact with respiratory secretions anticipated If tuberculosis is unlikely and no AIIRs or respirators are available, use Droplet Precautions instead of Airborne Precautions Tuberculosis more likely in HIV-infected than in HIV-uninfected persons
Cough, fever, or pulmonary infiltrate in any lung location in a patient with a history of recent travel (10–21 days) to a country with an outbreak of SARS or avian influenza	*M. tuberculosis,* severe acute respiratory syndrome virus–coronavirus (SARS-CoV), avian influenza	Airborne Precautions plus Contact Precautions in addition to eye protection If SARS and tuberculosis unlikely, use Droplet Precautions instead of Airborne Precautions
Respiratory infections, particularly bronchiolitis and pneumonia, in infants and young children	Respiratory syncytial virus, parainfluenza virus, adenovirus, influenza virus, human metapneumovirus	Contact Precautions plus Droplet Precautions Droplet Precautions can be discontinued when adenovirus and influenza have been ruled out
SKIN OR WOUND INFECTION		
Abscess or draining wound that cannot be covered	*Staphylococcus aureus* (MSSA or MRSA), group A streptococcus	Contact Precautions Add droplet precautions for the first 24 hr of appropriate antimicrobial therapy if invasive group A streptococcal disease is suspected

[a] Infection control professionals should modify or adapt this table according to local conditions. To ensure that appropriate empiric precautions are always implemented, hospitals must have systems in place to evaluate patients routinely according to these criteria as part of preadmission and admission care.

[b] Patients with the syndromes or conditions listed may have atypical signs or symptoms (e.g., neonates and adults with pertussis may not have paroxysmal or severe cough). The clinician's index of suspicion should be guided by the prevalence

of specific conditions in the community, as well as clinical judgment.

[c] The organisms listed under the column "Potential Pathogens" are not intended to represent the complete, or even most likely, diagnoses, but rather possible etiologic agents that require additional precautions beyond standard precautions until they can be excluded.

[d] These pathogens include enterohemorrhagic *Escherichia coli* O157:H7, *Shigella* spp., hepatitis A virus, noroviruses, rotavirus, and *Clostridium difficile.*

AIIR, airborne infection isolation room; CDC, Centers for Disease Control and Prevention; CoV, coronavirus; HIV, human immunodeficiency virus; MRSA, methicillin-resistant *Staphylococcus aureus;* MSSA, methicillin-susceptible *Staphylococcus aureus;* SARS, severe acute respiratory syndrome; VHF, viral hemorrhagic fever; WHO, World Health Organization.

Environmental Measures

Contaminated environmental surfaces and noncritical medical items have been implicated in transmission of several infectious agents, including VRE, *C. difficile, Acinetobacter* spp., MRSA, and RSV in healthcare settings.[4,85,86] Pathogens on surfaces are transferred to the hands of HCP and are then transferred to patients or items to be shared. Occupying a room previously occupied by a patient with a key pathogen is a risk factor for acquiring that pathogen during a hospital stay. Most often, the failure to follow recommended procedures for cleaning and disinfection contributes more than does the specific pathogen to the environmental reservoir during outbreaks. Education of environmental services personnel combined with direct observation and feedback was associated with a persistent decrease in VRE acquisition in a medical ICU. Use of a standardized cleaning checklist and implementation of monitoring for adherence to recommended environmental cleaning practices are important determinants of success. Visual markers (e.g., invisible fluorescein powder) and adenosine triphosphate bioluminescence technologies are also useful for monitoring effective environmental cleaning and providing immediate feedback to workers.[87] A program of environmental cleaning should be developed collaboratively by the IPC and environmental services departments. Certain infectious agents (e.g., rotavirus, noroviruses, *C. difficile*) can be resistant to some routinely used hospital disinfectants; thus when ongoing transmission occurs despite appropriate cleaning procedures, a 1 :

10 dilution of 5.25% sodium hypochlorite (household bleach) or other special disinfectants are indicated.

"No-touch" automated room decontamination technologies have been developed and added to room turnover procedures in some facilities. Ultraviolet light irradiation and hydrogen peroxide vapor systems have been shown to reduce surface contamination with common pathogens and decrease the risk of acquiring HAIs caused by those pathogens when these systems are added to a terminal cleaning regimen.[85–87] At specific wavelengths, ultraviolet light breaks the molecular bonds in DNA, thus destroying the organisms. Ultraviolet technology also has been considered as a method of disinfecting PPE, as a risk mitigation strategy for HCP caring for patients with EVD.[88] These technologies supplement, but do not replace, standard cleaning and disinfection because surfaces must be physically cleaned of particulate matter and debris. Other disadvantages of these systems are that they cannot be used when people are in the rooms, room turnover is delayed, and the systems are expensive to purchase. No recommendations have been made for routine use or specific indications because research on antimicrobial effectiveness, cost effectiveness, and feasibility of these systems is ongoing.

Self-disinfecting surfaces can be created by altering the structure of the surface material or by incorporating a material that has antimicrobial activity.[85–87] Copper has antimicrobial activity against a wide range of organisms including bacteria and fungi. Thus, incorporating copper into high-touch surfaces such as toilet seats, bed rails, door handles, or countertops is a novel infection prevention strategy that has been shown to reduce bacterial colony counts compared with control surfaces in healthcare settings.[89] However, no recommendation for routine use has yet been made.

Disinfection, Sterilization, and Removal of Infectious Waste

Disinfection and sterilization as they relate to IPC have been reviewed,[90] and the HICPAC/CDC developed comprehensive guidelines in 2008.[91] *Cleaning* is the removal of all foreign material from surfaces and objects. This process is accomplished using soap and enzymatic products. Failure to remove all organic material from items before disinfection and sterilization reduces the effectiveness of these processes. *Disinfection* is a process that eliminates all forms of microbial life except the endospore. Disinfection usually requires liquid chemicals. Disinfection of an inanimate surface or object is affected adversely by the following: the presence of organic matter; a high level of microbial contamination; use of too dilute germicide; inadequate disinfection time; an object that can harbor microbes in protected cracks, crevices, and hinges; and pH and temperature.

Sterilization is the eradication of all forms of microbial life, including fungal and bacterial spores. Sterilization is achieved by physical and chemical processes such as steam under pressure, dry heat, ethylene oxide, and liquid chemicals. The Spaulding classification of patient care equipment as *critical, semicritical,* and *noncritical* items with regard to sterilization and disinfection is used by the CDC. *Critical items* require sterilization because they enter sterile body tissues and carry a high risk of causing infection if they are contaminated; *semicritical items* require disinfection because they may contact mucous membranes and nonintact skin; and *noncritical items* require routine cleaning because they come in contact only with intact skin. If noncritical items used on patients requiring Transmission-Based Precautions, especially Contact Precautions, must be shared, these items should be disinfected between uses. Guidelines for specific objects and specific disinfectants are published and updated by the CDC. Multiple published reports and manufacturers similarly recommend the use and reuse of objects with appropriate sterilization, disinfection, or cleaning recommendations. Recommendations in guidelines for reprocessing endoscopes to avoid contamination focus on training of personnel, meticulous manual cleaning, high-level disinfection followed by rinsing and air-drying, and proper storage.[92] However, outbreaks of MDR GNB infections associated with exposure to duodenoscopes used for retrograde cholangiopancreatography that have been reprocessed according to recommendations suggest a need for new endoscope reprocessing technologies.[51,93] These endoscopes have a complex design with long, narrow channels, crevices that are difficult to access with a cleaning brush, right-angle turns, and heavy microbial contamination following procedures. Until new methods are developed, meticulous adherence to recommended processes with enhancements should be followed. Medical devices that are designed for single use (e.g., specialized catheters, electrodes, biopsy needles) must be reprocessed by third parties or hospitals according to the guidance issued by the Food and Drug Administration (FDA) in August, 2000 with amendments in September, 2006; such reprocessors are considered and regulated as "manufacturers." Available data show that single-use devices reprocessed according to the FDA regulatory requirements are as safe and effective as new devices.

Deficiencies in disinfection and sterilization leading to infection have resulted either from failure to adhere to scientifically based guidelines or failures in the disinfection or sterilization processes. When such failures are discovered, an investigation must be completed, including notification of patients and, in some cases, testing for infectious agents. A guidance document for risk assessment and communication to patients in such situations is published.[94]

Healthcare facility waste is all biologic or nonbiologic waste that is discarded and not intended for further use. *Medical waste* is material generated as a result of use with a patient, such as for diagnosis, immunization, or treatment, and it includes soiled dressings and intravenous tubing. *Infectious waste* is that portion of medical waste that potentially could transmit an infectious disease. Microbiologic waste, pathologic waste, contaminated animal carcasses, blood, and sharps are all examples of infectious waste. Methods of effective disposal of infectious waste include incineration, steam sterilization, drainage to a sanitary sewer, mechanical disinfection, chemical disinfection, and microwave treatment. State regulations guide the treatment and disposal of regulated medical waste. Recommendations are available for developing and maintaining a program within a facility for safe management of medical waste.[95]

Visitation Policies

Special visitation policies are required in pediatric units, especially the high-risk units, because acquisition of a seemingly innocuous viral infection in neonates and in children with underlying diseases can result in unnecessary evaluations and empiric therapies for suspected septicemia as well as serious, life-threatening disease. All visitors with signs or symptoms of respiratory or gastrointestinal tract infection should be restricted from visiting patients in healthcare facilities. Increased restrictions may be required during a community outbreak (e.g., SARS, pandemic influenza, enterovirus D68). During respiratory virus season, the number of visitors can be limited and the age restriction increased. It is preferred for all visitors to be immunized against influenza during influenza season. Several children's hospitals provide influenza vaccine or tetanus, diphtheria, and acellular pertussis (Tdap) vaccine, or both, to household contacts at no charge, thereby supporting the cocooning strategy endorsed by the Advisory Committee on Immunization Practices and the American Academy of Pediatrics.[96]

For patients requiring Contact Precautions, the use of PPE by visitors is determined by the nature of the interaction with the patient and the likelihood that the visitor will frequent common areas on the patient's unit or interact with other patients and their families. It is important to distinguish parents or guardians from nonhousehold visitors when determining whether the visitor should wear PPE. The risk-benefit decision should weigh not only the specific pathogen in question, but also the effect of parental or guardian PPE on breastfeeding, bonding, and family participation in the child's medical care. For family members who are rooming in with children who have prolonged hospitalizations, restriction of visitation to other patients is emphasized. A SHEA expert guidance document has been published to summarize the principles to follow to prevent transmission of infectious agents by visitors to patients because few data are available to inform evidence-based recommendations.[97]

Although most pediatricians encourage visits by siblings in inpatient areas, the medical risk must not outweigh the psychosocial benefit. Families favorably regard sibling visitation, and no evidence indicates increased bacterial colonization or subsequent bacterial infection in the neonate or older child who has been visited by siblings. Strict guidelines for sibling visitation should be established and enforced in an effort to maximize visitation opportunities and minimize risks of transmission of infectious agents, most frequently viruses. The following recommendations regarding visitation can guide policy development:

1. Sibling visitation is encouraged in the well-child nursery and NICU, as well as in areas for care of older children.

2. Before visitation, parents should be interviewed by a trained staff nurse concerning the current health status of the sibling. Siblings should not be allowed to visit if they are delinquent in recommended vaccines, have fever or symptoms of an acute illness, or are within the incubation period following exposure to a known infectious disease. After the interview, the physician or nurse should place a written consent for sibling visitation in the patient's permanent record and a name tag indicating that the sibling has been approved for visitation for that day.

3. Asymptomatic siblings who recently were exposed to varicella but who previously were immunized can be assumed to be immune.

4. The visiting sibling should visit only his or her sibling and not be allowed in playrooms with groups of patients.

5. Visitation should be limited to periods of time that ensure adequate screening, observation, and monitoring of visitors by medical and nursing staff members.

6. Children should perform hand hygiene before and after contact with the patient or upon entry and departure from the patient's room.

7. During the entire visit, sibling activity should be supervised by parents or another responsible adult.

Animals in Healthcare Facilities

Animal-assisted therapy can be of substantial clinical benefit to the child hospitalized for prolonged periods; therefore it is important for healthcare facilities to provide guidance for safe visitation. Many zoonoses and infections are attributable to animal exposure (see Chapter 89). Most infections result from inoculation of animal flora through a bite or scratch or self-inoculation after contact with the animal, the animal's secretions or excretions, or contaminated environment. Although few data support a true evidence-based guideline for animal visitation (including personal pets) in healthcare facilities, updated expert guidance is provided in the SHEA Expert Guidance on Animals in Healthcare Facilities: Recommendations to Minimize Potential Risk, which includes a review of the literature related to animal-assisted activities.[98]

Prudent visitation policies should limit visitation to animals that: (1) are domesticated; (2) do not require a water environment; (3) do not bite or scratch; (4) can be brought to the hospital in a carrier or easily walked on a leash; (5) are trained to defecate and urinate outside or in appropriate litter boxes; (6) can be bathed before visitation; and (7) are known to be free of respiratory, dermatologic, and gastrointestinal tract disease. Despite the established risk of salmonellosis associated with reptiles (e.g., turtles, iguanas), many reports of outbreaks of invasive disease associated with reptiles continue to be published[99]; reptiles should be excluded from pet visitation programs, and families should be advised not to have pet reptiles in the home with young infants or immunocompromised persons. Exotic animals that are imported should be excluded because of unpredictable behavior and the potential for transmission of unusual pathogens (e.g., monkeypox in the US in 2003).[100,101] Visitation should be limited to short periods and confined to designated areas. Visiting pets must have a certificate of immunization from a licensed veterinarian. Children should observe hand hygiene after contact with animals. Most pediatric facilities restrict pet interaction with severely immunosuppressed patients and patients in ICUs.

Occupational Health

Occupational health and student health collaboration with the IPC department of a healthcare facility is required by the Occupational Safety and Health Administration. HCP are at increased risk of infection in hospitals caring for children because (1) children have a high incidence of infectious diseases, (2) personnel can be susceptible to many pediatric pathogens, (3) pediatric care requires close contact, (4) children lack good personal hygiene, (5) infected children can be asymptomatic, and (6) HCP are exposed to multiple family members who also may be infected.

The occupational health department is an educational resource for information on infectious pathogens in the healthcare workplace. In concert with the IPC service, occupational health provides preemployment education and respirator fit testing and annual retraining for all employees regarding routine health maintenance, available recommended and required vaccines, Standard and Transmission-Based Precautions, and exposure control plans. Screening for tuberculosis at regular intervals, as determined by the facility's risk assessment, can use either tuberculin skin testing or interferon-γ release assays.[102] With new pathogens being isolated, new diseases and their transmission described, and new prophylactic regimens and treatment available, it is mandatory that personnel have an up-to-date working knowledge of IPC and know where and what services, equipment, and therapies are available for HCP.

All HCP should be screened by history or serologic testing, or both, to document their immune status to specific agents, and immunization should be provided for the following for all employees who are nonimmune and who do not have contraindications to receiving the vaccine: diphtheria toxoid, hepatitis B virus, influenza (yearly), mumps, poliomyelitis, rubella, rubeola, varicella, and Tdap. The 2006 Advisory Committee on Immunization Practices recommendation to administer a single dose of Tdap to certain HCP was amended in 2011 to have no restriction based on age or time interval since the last Td dose. Providing vaccines at no cost to HCP increases acceptance.

Influenza vaccine coverage among HCP has increased over time to 77% overall for the 2014 to 2015 influenza season, with the highest coverage rate of 90% in HCP working in hospitals and the lowest rate of 64% in long-term care settings.[103] Although mandatory influenza vaccination programs for all employees in healthcare facilities are endorsed by many professional societies,[104,105] some facilities have had success using novel strategies that include incentives, without a mandate.[106] Publications from several large institutions, including children's hospitals, indicate that mandatory programs with only medical and religious exemptions are well received, and only rare employees are terminated for failure to be vaccinated.[107,108]

Special Concerns of Healthcare Personnel

HCP who have common underlying medical conditions should be able to obtain general information on wellness and screening when needed from the occupational health service. HCP with direct patient contact who have infants <1 year of age at home often are concerned about acquiring infectious agents from patients and transmitting them to their susceptible children. An immune healthcare worker who is exposed to VZV does not become a silent "carrier" of VZV. However, pathogens to which the healthcare worker is partially immune or nonimmune can cause a severe, mild, or asymptomatic infection in the employee that can be transmitted to family members. Examples include influenza, pertussis, RSV and other respiratory viruses, norovirus, and tuberculosis. Important preventive procedures for HCP with infants at home or who are pregnant are as follows: (1) consistent training and observance of Standard Precautions, Transmission-Based Precautions, and especially hand hygiene according to published recommendations; (2) annual influenza and 1-time Tdap immunization (unless pregnant, when a Tdap immunization during each pregnancy is recommended); (3) routine tuberculosis screening; (4) assurance of immunity or immunization against poliomyelitis, measles, mumps, hepatitis B, and rubella; (5) early medical evaluation for acute infectious illnesses; (6) routine, on-time immunization of infants; and (7) prompt initiation of prescribed prophylaxis or therapy following exposure or development of certain infections.

HCP who are, could be, or anticipate becoming pregnant should feel comfortable working in the healthcare workplace. In fact, with Standard Precautions and appropriate adherence to environmental cleaning and isolation precautions, vigilant HCP can be at less risk than a preschool teacher, childcare provider, or mother of children with many playmates in the home. Pathogens of potential concern to pregnant HCP include cytomegalovirus, hepatitis B virus, influenza, measles, mumps, parvovirus B19, rubella, VZV, *M. tuberculosis*, and, since 2015, Zika virus. The causal association between Zika virus and microcephaly and other neurodevelopmental abnormalities[109] has led to recommended precautions. Although Zika virus is more frequently acquired outside of healthcare, pregnant HCP are advised to follow safe injection practices for prevention of exposure to infectious blood.[4] Pregnancy is an *indication* for influenza vaccine to prevent the increased risk of serious disease and hospitalization that occurs in women who develop influenza in the second or third trimester of pregnancy. In 2011, the CDC recommended universal immunization with Tdap (if previously not immunized with Tdap) for pregnant women after 20 weeks of gestation, and since 2012, the CDC recommends a dose of Tdap with each pregnancy.[110] Pregnant workers should assume that all patients potentially are infected with cytomegalovirus and other "silent" pathogens and should use hand hygiene and gloves when handling body fluids, secretions, and excretions. Table 2.4 summarizes information about infectious agents that are relevant to the pregnant woman working in healthcare. Chapters on each agent may be consulted for more specific information.

TABLE 2.4

Pregnant Healthcare Personnel: Guide to Management of Occupational Exposure to Selected Infectious Agents

Agent or Disease	In-Hospital Source	Potential Effect on the Fetus	Perinatal Transmission	Maternal Screening
Bordetella pertussis **Pertussis ("whooping cough")**	Respiratory droplets from a coughing patient, HCP, visitor	No congenital syndrome	Maternal respiratory secretions	Documenta of date of vaccination Tdap Tdap recommen during eac pregnancy. Past histor pertussis d is *not* prote and does n replace vac
Cytomegalovirus (CMV)/congenital infection syndrome[a], hearing loss	Patient populations: neonates, toddlers in childcare, hemodialysis patients, immunocompromised hosts, transplant recipients HCP acquisition during pregnancy unlikely to be occupational	Symptomatic congenital infection syndrome[a] 5%–10%; hearing loss 10%–15%; asymptomatic congenital infection; hepatitis, anemia, thrombocytopenia Hearing loss can have later onset	Primary infection 25%–50% Recurrent infection or second infection with new strain: 69% reduction in risk of transmission	Routine screening n recommen Preexisting maternal antibody incomplete protective fetus

	Urine, saliva, blood, semen, vaginal secretions, breast milk, respiratory secretions if pneumonia present		Symptomatic <5%–15%	
Ebola virus	Blood and body fluids from infected, clinically ill patients, especially large-volume diarrhea	Spontaneous abortion, stillbirth Neonatal survival rare.	Data on perinatal transmission limited and anecdotal; likely very high because Ebola virus is present in products of conception when tested	Routine screening n recommenc but a low threshold f diagnosing in the preg woman is recommenc PCR on blo the recommenc diagnostic Case fatalit of EVD in pregnant women is 9
Hepatitis A virus (HAV)	Feces (most common), highest titer just before onset of jaundice; blood *very* rare Transmission in healthcare settings rare	None; transmission can occur at the time of delivery if mother still in the infectious phase and can cause hepatitis in infant	None	Routine screening n recommenc
Hepatitis B virus (HBV)	Blood, body fluids, vaginal secretions, semen	Hepatitis; if acquired perinatally or at young age, increased risk for hepatocellular carcinoma	HBeAg$^-$ and HBsAg$^+$ (10%) HBeAg$^+$ and HbsAg$^+$ (90%)	Routine H testing adv Documenta of vaccinati
Hepatitis C virus (HCV)	Blood, body fluids	Hepatitis	Transmission 5% (range 0% –25%)	Screening c risk factors present: illi drug user (mother or

				partner wh illicit IV dr user); histo organ trans transfusion blood or bl products be 1992; hemodialys HBV or HI infection; unexplaine elevation o serum hepa enzymes; h of tattooing with histor percutaneo exposure to blood test f HCV antibo positive, H RNA)
Herpes simplex virus (HSV) **Fever blisters, cold sores, genital ulcers, encephalitis**	Vesicular fluid, oropharyngeal and vaginal secretions, amniotic fluid	Sepsis, encephalitis, meningitis, mucocutaneous lesions, congenital malformation (rare)	Primary genital infection 33%–50% Recurrent genital infection 1%–2%	Routine antibody te minimally useful Maternal ty specific ser for HSV-1 a HSV-2 antibodies should be considered when evalu an asymptoma neonate following vaginal or cesarean delivery to women wit genital lesio that are characterist HSV
Human immunodeficiency virus (HIV) **Acquired immunodeficiency syndrome (AIDS)**	Blood, body fluids, vaginal secretions, semen	No congenital syndrome Transmission primarily during delivery If infected, onset of symptoms usually at 12–18 months of age	Risk of transmission determined by maternal HIV viral load, duration of exposure to maternal blood, body fluids (including breast milk),	Routine pre screening advised wi repeat at er pregnancy high-risk behaviors HIV-expose infants who receive AR from birth: repeated sc

			and use of ART during pregnancy, labor, and postnatally in the infant If no ART: maternal viral load <1000 copies/mL virus, rate of 2%; if load ≥10,000, rate up to 25% Rate reduced to <3% with perinatal and neonatal ART	during firs HIV antibo screen wit fourth-generation if positive, quantitativ PCR
Influenza virus **Influenza (flu)**	Respiratory droplets or sneezing; coughing patient, HCP, visitor	No congenital syndrome Influenza in mother can cause fetal hypoxia, premature labor, and fetal death Increased morbidity during third trimester of pregnancy Increased morbidity and mortality in pregnant women with 2009 influenza A (H1N1)	Maternal respiratory secretions	Documenta of vaccine received du current sea

Measles (rubeola)	Respiratory secretions, coughing patient	Prematurity, spontaneous abortion; no congenital syndrome	Rare	Serology (I question af exposure, b not routine checked if adequate documenta provided Provider-documente disease or 2 doses meas containing vaccine ≥12 months of a
***Mycobacterium tuberculosis*, active disease (tuberculosis [TB])**	Sputum, skin lesions, CSF if meningitis present	Neonatal tuberculosis; liver most frequently infected	Rare	PPD, IGRA (interferon-release assa e.g., Quantiferoı Gold, T-Spo Chest radiograph indicated clinically or past known positive PP IGRA resul
***Neisseria meningitidis*, meningococcal disease, meningococcal meningitis, sepsis**	Blood, respiratory secretions	No congenital syndrome Fetus at risk if mother develops severe disease during pregnancy	Rare	No routine screening
Parvovirus B19 Fifth disease (slapped cheeks), anemia, fetal	Respiratory secretions; blood of immunocompromised patients and patients	Fetal hydrops, stillbirth No congenital syndrome	Rare	No routine screening. Parvovirus DNA can b

hydrops	with sickle cell disease during aplastic crisis Patient with Fifth disease no longer contagious once rash appears	Approximately 25% Fetal death <10%		detected in serum, leukocytes, respiratory secretions, tissue speci Specific Ig IgG if expo has occurre
Rubella	Respiratory secretions	Congenital infection syndrome[a] 90% affected in first trimester 40%–50% affected overall	Rare	Documenta of 2 doses rubella-containing vaccine beforepreg Routine ru IgG testing during pregnancy Preconcept screening recommen
Syphilis **Rash, skin and genital lesions, central nervous system disease**	Blood, lesion (especially large bullae of congenital syphilis), amniotic fluid	Congenital infection syndrome[a] Variable 10%–90%; depends stage of maternal disease and trimester of the infection	Transmission possible, related to contagiousness of maternal lesions	Serum VD RPR Serum FTA
Varicella zoster virus (VZV) **Chickenpox, shingles**	Respiratory secretions, vesicle fluid	Congenital infection syndrome Malformations, skin, limb, CNS, eye: chickenpox zoster	High risk of infection and severe disease if maternal varicella within 5 days	Varicella Ig serology Past history chickenpox unreliable

		Congenital syndrome 2%	before or 2 days after delivery	
Zika virus	Blood, body fluids of infected patients; mosquitoes in endemic area. Acquisition in the community more likely than in healthcare settings	Microcephaly, other neurodevelopmental abnormalities	Undefined at time of publication	rt-PCR on Serum IgG,

[a] Congenital syndrome: varying combinations of jaundice, hepatosplenomegaly, microcephaly, thrombocytopenia, anemia, retinopathy, skin and bone lesions, and “blueberry muffin spots” (extramedullary hematopoiesis).

[b] Live virus vaccine given before or after pregnancy.

ART, antiretroviral therapy; CDC, Centers for Disease Control and Prevention; CNS, central nervous system; CSF, cerebrospinal fluid; EVD, Ebola virus disease; FTA-ABS, Fluorescent treponema antigen-antibody test; HBeAg, hepatitis B e antigen; HBIG, hepatitis B immune globulin; HBsAg, hepatitis B surface antigen; HCP, healthcare personnel; IgG, immunoglobulin G; IgM, immunoglobulin M; IGIV, immune globulin intravenous; IM, intramuscular; IV, intravenous; PCR, polymerase chain reaction; PPD, purified protein derivative; RPR, rapid plasma reagin test; Tdap, tetanus-diphtheria-acelluar pertussis; VDRL, Venereal Disease Research Laboratory test; WHO, World Health Organization.

Infection Prevention and Control in the Nonacute Care Setting

The risk of HAIs in pediatric ambulatory settings is substantial, and it usually is associated with lack of adherence to routine IPC practices and procedures, especially disinfection, sterilization, and hand hygiene. Respiratory viral agents and *M. tuberculosis* are noteworthy pathogens transmitted in ambulatory settings. Transmission of RSV in an HSCT outpatient clinic has been demonstrated using molecular techniques.[111] Crowded waiting rooms, toys, furniture, lack of isolation of children, unwell children, contaminated hands, contaminated secretions, and susceptible HCP are only some of the factors that result in sporadic and epidemic illness in outpatient settings. The association of community-associated MRSA in HCP working in an outpatient HIV clinic with environmental community-associated MRSA contamination of that clinic indicates the potential for transmission in this setting.[112] Patient-to-patient transmission of *Burkholderia* species and *P. aeruginosa* in outpatient clinics for patients with cystic fibrosis has been confirmed and prevented by implementing recommended IPC methods.[9] IPC guidelines and policies for pediatric outpatient settings, including office practices, were published by the American Academy of Pediatrics in 2007,[113] reaffirmed in 2015, and are updated currently. Prevention strategies include definition of policies, education, and strict adherence to guidelines. In pediatrics, among the most important interventions are separation of children with respiratory tract illnesses from well children and consistent implementation of respiratory etiquette or cough hygiene. A guideline for IPC for outpatient settings with a checklist and a guideline for outpatient oncology settings can be found on the CDC website.[114] Principles and recommendations for Safe Living after HSCT[115] and for patients with cystic fibrosis[9] are valuable contributions to management of infectious risks for specific populations in the ambulatory setting. A guideline based on data and expert consensus opinion for IPC in residential facilities for pediatric patients and their families provides practical guidance for settings where high-risk patients live with their families for varying periods of time.[116] IPC challenges now are being addressed in long-term care facilities for children.[117] More data are needed to determine the most effective and least restrictive practices.

Infections Associated With Group Childcare

Jennifer P. Collins, Andi L. Shane

On average, 12.5 million (61%) of the 20.4 million children in the United States who are younger than 5 years of age were enrolled in a regular childcare arrangement during the spring of 2011.[1] Group childcare settings can increase the frequency of certain infectious diseases and amplify outbreaks of illness (Table 3.1). Aggregation of young children potentiates transmission of organisms that can produce disease in other children, adult care providers, parents, and community contacts. Children newly entered into group childcare are at especially high risk of enteric and respiratory tract infections. However, mothers whose children were enrolled in group childcare before 2.5 years of age reported their children had less frequent respiratory and gastrointestinal tract infections and episodes of otitis media during elementary school years.[2] A longitudinal repeated-event analysis of 3963 newborns followed for 8 years found that children who were enrolled in childcare at <2 years of age had more episodes of wheezing in the first years of life; however, among those children without older siblings, wheezing episodes and steroid use between ages 4 and 8 years were reduced compared with children who were not enrolled in childcare at an early age. Overall, early childcare was not found to be protective against asthma symptoms, airway hyperresponsiveness, or allergic sensitization when children were assessed at 8 years of age.[3] An increase in antibiotic use as an attempt to facilitate earlier return to care enhances the potential for emergence of resistant organisms, thus resulting in an increased economic burden to individual persons and society.[4–6] Despite the challenges of frequent respiratory and gastrointestinal illness exacerbations among children enrolled in group childcare, these arrangements facilitate opportunities for socialization and enable primary caregivers to be employed outside the home.

TABLE 3.1

Association of Infectious Diseases With Group Childcare Settings

Disease or Infection	**Risk Factors and Association With Outbreaks**
Enteric	Close person-to-person contact, fecal-oral contact, suboptimal hand hygiene and food preparation practices
Viral	
Rotaviruses, enteric adenoviruses, astroviruses, noroviruses, hepatitis A virus (HAV)	Commonly associated with outbreaks; HAV and rotavirus vaccine preventable
Bacterial	
Shigella spp., *Escherichia coli* O157:H7	Commonly associated with outbreaks
Campylobacter spp., *Salmonella* spp., *Clostridium difficile*	Less commonly associated with outbreaks
Parasitic	
Giardia intestinalis	Commonly associated with outbreaks
Cryptosporidium parvum	
Respiratory tract (acute upper and lower respiratory tract infections and invasive disease)	Aerosolization and respiratory droplets, person-to-person contact, suboptimal hand hygiene
Bacterial	
Haemophilus influenzae type b (Hib)	Few outbreaks; vaccine preventable
Streptococcus pneumoniae	Few outbreaks; vaccine preventable; invasive *S. pneumoniae* caused by serotypes not in vaccine
Group A streptococcus	Few outbreaks and low risk of secondary cases
Neisseria meningitidis	Few outbreaks; some serogroups vaccine preventable
Bordetella pertussis	Increasingly associated with outbreaks in childcare centers and schools; vaccine preventable
Mycobacterium tuberculosis	Occasional outbreaks, usually as a result of contact with an infectious adult care provider
Kingella kingae	Outbreaks rare; oropharynx usual habitat; usually manifest as arthritis and osteomyelitis
Viral	
Rhinoviruses, parainfluenza, influenza, respiratory syncytial virus (RSV), respiratory adenoviruses, influenza, metapneumoviruses, bocavirus	Disease usually caused by same organisms circulating in the community; influenza vaccine preventable in children ≥6 months of age

Multiple organ systems	
Cytomegalovirus	Prevalent; asymptomatic excretion with transmission from children to providers
Parvovirus B19	Outbreaks reported; risk to susceptible pregnant women and immunocompromised
Varicella-zoster virus (VZV)	Outbreaks in childcare centers occur; vaccine preventable in children ≥12 months of age; zoster lesions present low risk of infection
Herpes simplex virus (HSV)	Low risk of transmission from active lesions and oral secretions
Hepatitis B virus	Rarely occurs in childcare centers; vaccine preventable
Hepatitis C virus	No documented cases of transmission in the childcare setting
Human immunodeficiency virus (HIV)	No documented cases of transmission in the childcare setting
Skin	Close person-to-person contact
Staphylococcal and streptococcal impetigo	Transmission increased by close person-to-person contact with lesions; outbreaks less likely with decreased incidence of varicella infections; methicillin-resistant *Staphylococcus aureus* (MRSA) infection common
Scabies	Outbreaks in group childcare reported
Pediculosis	Common in children attending group childcare
Ringworm	Tinea corporis and tinea capitis outbreaks associated with childcare
Conjunctiva	Outbreaks in group childcare reported with both bacterial and viral causes

Childcare Settings

Quantifying the number of children participating in each type of childcare setting is challenging because of different ascertainment methods used in several data sources. Types of facilities can be classified by size of enrollment, age of enrollees, and environmental characteristics of the facility. Grouping of children by age varies by setting, but in organized care facilities children usually are separated into the following groups: infants (6 weeks through 12 months), toddlers (13 through 35 months), preschoolers (36 months through 59 months), and school-aged children (5 through 12 years). These designations have relevance to infectious disease epidemiology as well as regulation and monitoring. Most nonrelative care provided in an organized care facility is subject to state licensing and regulation, whereas care by a relative in a child's or provider's home is usually not subject to state regulations and monitoring.

The United States Census Bureau conducts the Survey of Income and Program Participation (SIPP), which collects information about childcare arrangements for children <15 years of age. In 2011, 51% of children <5 years of age with working mothers were cared for by a relative, 33% were in organized care including center-based care or family childcare homes, 27% had multiple arrangements, and 11% did not have a regular childcare arrangement, with some survey respondents selecting more than 1 option.[1]

Epidemiology and Etiology of Infections

Although most infectious organisms can be associated with outbreaks in settings that do not involve childcare, many agents have the propensity to propagate in childcare settings (see Table 3.1.)

Enteric Infections

Enteric viruses are the predominant cause of diarrheal syndromes among children in group childcare.[7] Outbreaks of diarrhea occur at a rate of approximately 3 per year per childcare center and are associated most frequently with organisms that cause infection after ingestion of a low inoculum. These organisms generally are transmitted from person to person and include rotavirus, norovirus, sapovirus, astrovirus, enteric adenovirus, *Giardia intestinalis, Cryptosporidium, Shigella* spp., *Escherichia coli* O157:H7, other Shiga toxin–producing *E. coli* (STEC), *E. coli* O114, and enteropathogenic *E. coli.* These fecal coliforms and enteric viruses contaminate the environment with greater frequency during outbreaks of diarrhea. In a prospective study of acute gastroenteritis in childcare centers, viruses isolated from the stool of children with diarrhea also were detected on environmental surfaces in 45% of outbreaks.[8] The inoculum associated with diarrhea, the attack rates, and the frequency of asymptomatic excretion of organisms for common enteric infections in childcare settings are shown in Table 3.2. Reported attack rates depend on several factors, including methods used for organism detection.

TABLE 3.2

Organism	Inoculum Required to Cause Diarrhea in Adult Volunteers	Attack Rate in Enrollees (%)	Secondary Attack Rate in Family Members (%)	Asymptomatic Excretion in Enrollees
Rotavirus	18–1000 virions	50	15–80	Common
Enteric adenovirus	Unknown	40	Unknown	Common
Astrovirus	Unknown	50–90	Unknown	Common
Calicivirus	Unknown	50	Unknown	Common
Giardia intestinalis	10^{1-2} cysts	17–54	15–50	Common
Cryptosporidium	132 oocysts	33–74	25–60	Common
Shigella	10^{1-2}	33–73	25–50	Uncommon
Escherichia coli	10^{8}			
O157:H7		29, 34	Unknown	Uncommon
O114:NM		67	Unknown	Uncommon
O111:K58		56, 94	Unknown	Uncommon
Clostridium difficile	Unknown	32	Unknown	Common

Organisms generally associated with foodborne outbreaks, including *Salmonella* spp. and *Campylobacter jejuni,* are infrequently associated with diarrhea in the childcare setting. However, reports of childcare outbreaks of diarrhea in association with ingestion of fried rice contaminated with *Bacillus cereus,*[9] and of norovirus infection in association with frozen strawberries,[10] highlight the issue that foodborne outbreaks can occur in the childcare setting, especially when food is prepared and served at the childcare center.

Spread of diarrheal pathogens from index cases in the childcare setting to family members has been reported for many enteropathogens (see Table 3.2), with secondary attack rates ranging from 15% to 80%. During outbreaks of diarrhea in childcare centers, asymptomatic excretion of enteropathogens is frequent (see Table 3.2). In a longitudinal study of serial stool samples collected from 82 children <2 years of age in a childcare center, enzyme immunoassay revealed that 21 of 27 (78%) children from whom *G. intestinalis* was detected and 19 of 37 (51%) children from whom rotavirus was detected were asymptomatic.[11] A point-prevalence evaluation of 230 asymptomatic preschool children attending childcare in southwest Wales and inner London demonstrated a 1.3% fecal colonization rate with both *Cryptosporidium* and *Giardia* spp.[12] The role that asymptomatic excretion of enteropathogens plays in spread of disease is unknown.

Acute infectious diarrhea is 2 to 3 times more common in children enrolled in out-of-home childcare than in age-matched children cared for at home.[13–15] Approximately 20% of outpatient visits for acute diarrheal illness among children younger than 3 years of age are attributable to childcare attendance.[13] In addition, the incidence of diarrheal illness is threefold higher among children during their first month in out-of-home childcare compared with children cared for at home.[13,16,17]

Diarrhea occurs 17 times more frequently in diapered children than in toilet-trained children.[17] Higher attack rates among diapered children may represent exposure of a younger, nonimmune cohort. In contrast, in a multicommunity group childcare outbreak of *Shigella sonnei*, the highest attack rates were noted in rooms where both toilet-trained and diapered children were co-mingled (14%) compared with rooms with toilet-trained children only (9%) and rooms with diapered children only (5%), despite comparable availability of sinks and toilets.[18] The likely reason for this finding was that the toilet-trained children were acquiring continence, and the diarrhea resulting from their shigellosis made them incontinent. Investigators in North Carolina demonstrated that adherence to proper diapering and hand hygiene practices and use of dedicated food preparation equipment decreased the incidence of diarrheal illness among children and staff in out-of-home childcare centers.[19]

Enteric Viral Infections

Rotavirus.

In the prerotavirus vaccine era, rotaviruses were the most common cause of significant symptomatic diarrhea in children <2 years of age. Person-to-person transmission by the fecal-oral route predisposes nonimmune infants and young children and their childcare providers to rotavirus infection. Because rotavirus can be isolated from human stools for approximately 21 days after illness onset and rotavirus RNA can be detected on toys and surfaces in childcare centers, this organism has been associated with outbreaks of diarrhea in the childcare setting.[20]

Primary prevention of rotavirus in all settings is accomplished with the completion of an oral rotavirus vaccine series. The universal uptake of rotavirus immunization in the US has changed the epidemiology of rotavirus infections and has resulted in a greatly reduced burden of disease and consequently fewer childcare-associated outbreaks.[21] Pediatric rotavirus immunization has also provided indirect protection to adults, with a decline in peak prevalence by nearly 50% in 1 study.[22] Rotavirus-immunized childcare enrollees can therefore provide indirect protection to rotavirus-nonimmune childcare providers, thus reducing opportunities for person-to-person transmission.

Norovirus.

In the postrotavirus vaccine era, norovirus has become the leading cause of acute gastroenteritis in young children. A population-based surveillance study of children younger than 5 years of age with acute gastroenteritis who presented for medical care in 3 counties surrounding Nashville, Tennessee, Cincinnati, Ohio, and Rochester, New York in 2009 and 2010 detected norovirus in 278 (21%) of 1295 stool specimens, compared with rotavirus in 152 (12%).[23]

Several features of norovirus facilitate its spread, including the low inoculum required for transmission (approximately 18 to 1000 virions), asymptomatic shedding that can precede and extend beyond symptom duration (in up to 30% of infections), tolerance to a wide range of temperatures that facilitates persistence on environmental surfaces, and strain-specific immunity.[24] Outbreaks can occur in a variety of settings including childcare centers, long-term care facilities, hospitals, restaurants, and cruise ships. Two epidemiologic studies of norovirus gastroenteritis in Germany and Japan found that genogroup GII strains predominated in outbreaks associated with childcare facilities while these strains were circulating in the community.[25,26]

Hepatitis A Virus.

Hepatitis A virus (HAV) infections usually are mild or asymptomatic in children, and outbreaks in childcare centers generally are not recognized until illness becomes apparent in older children or adults. The first outbreak of HAV infection in a childcare center was reported in 1973 in North Carolina,[27] with subsequent outbreaks recognized throughout the US.[28] Before routine immunization of children with hepatitis A vaccines in the

US, approximately 15% of HAV infections were estimated to be associated with childcare centers. Uptake of universal hepatitis A immunization in children has correlated with a decreasing proportion of outbreaks among children in childcare and elementary school settings, as well as among adults who have contact with children enrolled in childcare centers.[29,30]

Peak viral titers in stool and greatest infectivity with hepatitis A occur during the 2 weeks before onset of symptoms. HAV infections are transmitted in the childcare setting by the fecal-oral route and occur more frequently in settings that include diapered children. The mainstays of prevention of HAV infection include maintenance of personal hygiene, hand hygiene, disinfecting procedures, and immunization.

The US Centers for Disease Control and Prevention (CDC) recommend hepatitis A vaccine for all children beginning at 1 year of age, with the 2 doses administered 6 to 18 months apart.[31] Administration of hepatitis A vaccine to unimmunized, immunocompetent people 12 months through 40 years of age also is recommended for postexposure prophylaxis (PEP).[32,33] The CDC advises that vaccine PEP be administered to all previously unvaccinated staff and attendees of childcare centers or homes when 1 or more HAV infections are identified in children or employees or when an HAV infection is recognized in 2 or more households of center attendees. In centers that provide care only to toilet-trained children, PEP need be administered only to unimmunized classroom contacts of the index child. If an HAV infection is identified in 3 or more households, PEP should be considered for members of households with diapered children attending the childcare center.[34] Standard immune globulin (IG) is no longer recommended for HAV PEP in the US in most situations. Despite the decline in the incidence of HAV, continued education, training, and monitoring of staff regarding appropriate hygienic practices are essential components of any prevention plan.

Enteric Bacterial Infections

Escherichia coli.

Bacterial pathogens that have the potential to cause severe systemic infections, including *E. coli* O157:H7 and other Shiga toxin–

producing *E. coli* (STEC) strains, have been associated with fecal-oral transmission in group childcare settings. An epidemiologic study of non–O157 STEC outbreaks in the US found that 15 (39%) occurred through person-to-person transmission, with 13 (87%) of those occurring in childcare centers.[35] In an outbreak of *E. coli* O157:H7 infection in a childcare center in Bronx, New York, 11 of 45 attendees tested positive for *E. coli* O157:H7 by stool culture or Shiga-like toxin assay.[36] The original source of the outbreak was not determined; however, multiple sanitary violations were identified, including improper disinfection of diaper changing tables, lack of sanitary distribution of food, and inadequate exclusion of attendees who had diarrheal illnesses. After 2 cases of STEC were identified at a childcare center in Norway, an outbreak investigation found 9 additional cases among the 91 children enrolled and 1 case among the 41 employees; no evidence of common exposures was found, and person-to-person transmission was determined to be likely. Three of the persons with cases were asymptomatic, a finding that raises important questions regarding the utility of exclusion policies and screening of asymptomatic contacts.[37]

Shigella sonnei.

S. sonnei causes periodic multicommunity outbreaks in group childcare settings. Childcare attendance and age <60 months were associated with illness in a community outbreak of *S. sonnei* among traditionally observant Jewish children in New York City in 2000.[38] Multiple illnesses in a single household were determined to result from intrahousehold secondary transmission. A multicommunity outbreak of more than 1600 culture-confirmed cases in the greater metropolitan area of Cincinnati, Ohio in 2001 had an overall mean attack rate of 10% among childcare center enrollees. The highest attack rates occurred among newly or incompletely toilet-trained enrollees, and the lowest attack rates were noted among diapered children. The attack rate was 6% among staff members. Secondary transmission was facilitated by poor hygiene practices, including inaccessible handwashing supplies and incomplete diaper disposal practices, as well as through recreational activities involving water.[18] A prolonged multistate increase of shigellosis caused by organisms with similar biochemical and genetic profiles occurred in the South and mid-Atlantic areas in 2001 to 2003. A substantial proportion of infections was associated with group childcare.[39] In 2005, 639 cases of multidrug-resistant *S. sonnei* were reported in northwest Missouri. A case-control investigation of 39 licensed childcare centers demonstrated that centers with ≥1 sink or a diapering station in each room were less likely to have cases, thus reinforcing the importance of environmental design and hygiene in reducing the propagation of shigellosis in childcare centers.[40] An observational study following a shigellosis outbreak in St. Louis, Missouri examined the utility of requiring a second negative convalescent stool culture among those excluded from work or childcare. Of the 172 people who submitted at least 2 follow-up cultures, the probability that *S. sonnei* was isolated from a second culture after being isolated from a first culture was 7%. All (100%) of the second cultures from people who had a first negative follow-up culture result were without growth of *S. sonnei*, a finding suggesting that a single negative convalescent culture result is sufficient to document clearance.[41]

Respiratory Tract Infections

Organisms responsible for respiratory tract infections in childcare settings are similar to organisms that circulate in the community and include respiratory syncytial virus (RSV), parainfluenza viruses, adenovirus, rhinovirus, coronavirus, influenza viruses, human metapneumovirus, bocavirus, parvovirus B19, and *Streptococcus pneumoniae.*

Children <2 years of age who are attending childcare centers have an increased number of upper and lower respiratory tract infections, including acute otitis media and pneumonia, compared with age-matched children cared for at home. Approximately 10% to 17% of respiratory tract infections in US children <5 years of age are attributable to childcare attendance.[42,43] A prospective cohort study found that 89% of disease episodes among children attending a childcare center are respiratory tract infections.[44] Another prospective cohort study following 119 childcare attendees through 24 months of age demonstrated a mean annual incidence of 4.2 respiratory tract infections per child during the first year of childcare enrollment and 1.2 per child during the second year of childcare enrollment. One or more viruses were detected by real-time reverse transcriptase polymerase chain reaction (real-time RT-PCR) from two thirds of the children with respiratory tract infections.[45] Molecular-based diagnostics have increased the yield of virus detection in children with respiratory tract infections. An epidemiologic study of childcare attendees with new-onset respiratory illness detected at least 1 virus in 84% and multiple viruses in 46% of cases using PCR. Children with multiple viruses detected at the onset of illness were less likely to have fever (odds ratio [OR] 0.6; 95% confidence interval [CI], 0.4–0.9) but more likely to have symptoms lasting >7 days (OR 1.9; 95% CI, 1.2–3.14).[46]

A national registry-based study of Danish children from birth to 5 years of age revealed that the first 6 months of enrollment in group childcare among children enrolled at ≤1 year of age were associated with a 69% higher incidence of hospitalizations for acute respiratory tract infections compared with age-matched children in home care. The incidence of hospitalization decreased after 6 months of group childcare enrollment and was comparable to that of children in home care after >12 months of enrollment.[47] A prospective study comparing children enrolled in childcare in the first year of life with those who were not found that childcare attendees had more episodes of physician-diagnosed upper respiratory tract infections and acute otitis media in their first year of life. Additionally, although the 2 groups had similar rates of illness over the entire 6-year study period, childcare attendees had increased visits to their general practitioner and an increased risk of specialist referral.[48]

The risk of acute otitis media is increased among children enrolled in childcare, especially those <2 years of age. In 1 study, the incidence of otitis media was 1.5 times higher among children enrolled in childcare compared with children in home care.[43] Acute otitis media is the most common reason for antibiotic use in children <3 years of age in the childcare setting. Childcare attendance has been associated with increased risk of recurrent acute otitis media (>6 episodes in 1 year) and chronic otitis media with effusion persisting for more than 6 months. After controlling for the total size of the childcare group for children younger than 12 months of age, the previously established relationship between attending out-of-home childcare and frequent ear infections was reduced from an OR of 3.2 (95% CI, 1.5–6.7) to and OR of 1.34 (not significant; P = 0.60).[49] Because acute otitis media usually is diagnosed empirically, the relative contribution of bacterial versus viral causes is largely unknown.

Handwashing decreases the frequency of acute respiratory tract infections in childcare.[50,51] A randomized controlled trial that included training childcare staff regarding handwashing, transmission modes of infection, and aseptic techniques related to nose wiping demonstrated a significant reduction in upper respiratory tract infections among enrollees <24 months of age.[50] A study to assess the potential role of clothing as a source of transmission of human rhinovirus found that teachers' clothing is unlikely to facilitate the transmission of rhinovirus in childcare settings. Symptomatic teachers are more likely to have rhinovirus in their nasal mucus and on clothing.[52] Because most infectious agents are communicable for a few days before and after symptoms, exclusion of children and teachers based on upper respiratory tract symptoms is unlikely to decrease transmission, and the continued practice of respiratory and hand hygiene is likely to be more effective in preventing spread.

Respiratory Viral Infections

Influenza Virus.

Rates of seasonal influenza are highest among children <2 years of age and older adults, and rates of complications are greatest among children of all ages with predisposing or underlying medical conditions. Among preschool-aged children with influenza virus infections, hospitalization rates range from 100 to 500 per 100,000 children, with the highest hospitalization rates among children from <1 year of age.[53] Influenza viruses are spread from person to person primarily through large respiratory tract droplets, either directly or by secondary contact with objects that are contaminated with infectious droplets. Children shed virus for several days before the onset of clinical symptoms and are contagious for >10 days following symptom onset. Transmission of infections can be increased by close contact among children who are not able to contain their secretions.

Annual vaccination of all people ≥6 months old is the primary method of preventing seasonal influenza infections.[54] A randomized controlled trial conducted during the 1996 to 1997 influenza season in 10 childcare centers in San Diego, California found that vaccinating children against influenza reduced influenza-related illness among their household contacts.[55–57] In addition to preventing respiratory tract illness, influenza vaccine prevents acute otitis media among children attending childcare, as shown by several studies.[50,51,58,59]

Routine use of intranasal influenza vaccine among healthy children can be cost effective and can be maximized by using group-based vaccination approaches. A prospective study of intranasal influenza vaccine in healthy children 15 through 71 months of age demonstrated clinical and economic efficacy when vaccination efforts were focused on children in group childcare settings.[60] Vaccinating children has been associated with indirect protection of older people as well.[60,61]

Mandatory influenza vaccination before childcare attendance can increase immunization coverage and consequently decrease infection. In 2010, Connecticut became the second state, after New Jersey, to require all children 6 to 59 months of age in licensed childcare programs to receive at least 1 dose of seasonal influenza vaccine annually.[62] Seasonal influenza vaccination rates among children 6 to 59 months of age in Connecticut increased from 68% in 2009 to 2010 to 84% in 2012 to 2013. Connecticut also was compared with the 10 other sites participating in the CDC Emerging Infections Program, none of which had an influenza vaccine mandate for childcare centers at the time. Between the 2007 to 2008 and the 2012 to 2013 seasons, Connecticut had the highest percentage of decrease in influenza-associated hospitalization rates; 9 of 10 sites without mandated influenza immunization for childcare attendees reported increasing influenza-associated hospitalization rates over this time period.

Childcare center closure as a strategy to prevent and monitor community spread of influenza was considered during the 2009 H1N1 influenza pandemic. Extrapolating to school-aged children, 58% of families of 402 students in Perth, Australia who were affected by pandemic-related school closures reported a substantial disruption of daily schedules. Almost one half of the parents had work absences, and 35% made alternative childcare arrangements. Children affected by the school closures were more likely to report out-of-home activities during the school closure period. Fewer than one half (47%) of the parent respondents believed that the school closures were an effective response in reducing the potential for community transmission.[63]

Respiratory Syncytial Virus.

RSV is among the most common causes of serious lower respiratory tract infections in young children, with an estimated 55,000 to 125,000 related hospitalizations and 200 to 500 RSV-related deaths annually in the US.[64] Attack rates as high as 98% have been reported after first exposure among children at risk for infection, with frequent reinfection (65% to 75%) on reexposure to RSV in the 2 years after initial exposure.[65]

A prospective cohort study of children 4 weeks to 30 months of age who were attending full-time childcare detected RSV by RT-PCR from 59 (11%) of the children with respiratory illnesses and multiple viruses in 42 (71%) of the patients with RSV. This study also found longer duration of symptoms and increased frequency of healthcare visits in RSV-positive children compared with RSV-negative children. Additionally, 2 clusters of RSV infection resulted in 50% of enrolled children infected within 6 days of the index case in each room. When molecular sequencing was performed in 1 cluster, the same strain of RSV was isolated in 5 (38%) of 13 illness episodes, a finding suggesting rapid child-to-child transmission.[66]

Respiratory Bacterial Infections

Pertussis.

Infections caused by *Bordetella pertussis* in the US have increased dramatically since 2000; 7867 cases were reported in 2000, 27,550 cases in 2010, and 28,660 cases in 2014.[67,68] Several pertussis epidemics have occurred since 2000, including outbreaks in Washington State in 2012 and in California in 2014.[69,70] These outbreaks have been attributed to inadequate vaccine coverage and waning immunity related to universal use of acellular pertussis vaccines.

Incompletely immunized infants often experience severe clinical disease from pertussis. In many group childcare settings, adolescents and adults with mild to moderate illnesses can be the source cases of pertussis. An outbreak of pertussis occurring in a childcare center in northern Israel with 88% immunization coverage resulted in *B. pertussis* detected by a positive culture or PCR result in all unvaccinated children and in 7% of vaccinated children.[71] In 2005, the CDC recommended that postpartum women and other contacts of newborn infants receive tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine (Tdap) vaccine to protect infants from pertussis exposure, a strategy known as cocooning.[72] In 2011, the CDC recommended that unvaccinated pregnant women receive a dose of Tdap to protect infants by transplacental maternal antibody transfer.[73] In 2012, the CDC expanded this recommendation to administration of Tdap immunization during the third trimester of every pregnancy.[74] Childcare providers of any age with routine contact with infants <12 months of age should receive a single dose of Tdap.[72]

Tuberculosis.

An adult or adolescent often is the index case for *Mycobacterium tuberculosis* infections in a group childcare setting; child-to-child transmission occurs infrequently. An outbreak of tuberculosis (TB) associated with a private-home childcare facility in San Francisco, California occurred between 2002 and 2004. Of 11 outbreak cases, 9 (82%) occurred in children <7 years of age; all these children had extensive contact through childcare in a private home, where the adult index patient spent considerable time. Isolates from 4 of the pediatric patients and 2 of the adult patients had identical molecular patterns. Additionally, 36 children and adult contacts had latent TB infection.[75] In an outbreak of TB following prolonged contact with a provider with cavitary disease in a childcare center in Sweden, 17 children had radiographic evidence of pulmonary disease; 1 child had miliary disease, and 17 had latent TB infection.[76] These outbreaks demonstrate that detection and contact investigations in childcare centers are paramount in reducing TB infection.

Group A *Streptococcus.*

Outbreaks of group A *Streptococcus* (GAS) infection among children and adult staff in childcare settings have been reported. In a study of prevalence of GAS conducted in a childcare center after a fatal case of invasive GAS disease, 25% of 258 children and 8% of 25 providers had GAS isolated from throat culture. Risk of carriage was increased in children who shared a room with the index case (OR, 2.7; 95% CI, 0.8–9.4).[77] Perianal GAS infection and infection associated with varicella also have been reported.[78,79] A clone of GAS (*emm* type 4) was responsible for a community outbreak of streptococcal toxic shock syndrome among children attending a childcare center in northern Spain. In this situation, the outbreak-associated strains were not isolated from pharyngotonsillar swabs of staff, childcare, or household contacts of the colonized and infected children.[80]

Invasive Bacterial Infections

Haemophilus influenzae Type b.

Studies conducted before routine use of *Haemophilus influenzae* type b (Hib) conjugate vaccine in the US showed that the risk of developing primary invasive Hib infection was higher among children attending childcare centers than in children cared for at home, independent of other possible risk factors. Incorporation of Hib conjugate vaccines into the routine immunization schedule of children in the US dramatically reduced the frequency of invasive Hib disease. Oropharyngeal carriage of *H. influenzae* non–type b was associated with childcare attendance exceeding 15 hours per week in an epidemiologic study in Minnesota from 2008 to 2009.[81] Despite its rising prevalence in other settings, nontypable *H. influenzae* has not been associated with childcare outbreaks.

Neisseria meningitidis.

Risk of disease caused by *Neisseria meningitidis* can be increased in group childcare settings. Using space-time cluster analysis of invasive infections during 9 years of surveillance from 1993 to 2001 in the Netherlands, researchers noted that clustering beyond chance occurred at a rate of 3% and concluded that this rate was likely the result of direct transmission. Childcare center attendance was reported as the likely exposure for 8 of 40 (20%) clusters, thus accounting for 13 of 82 (16%) cases of invasive disease with multiple serosubtypes.[82] For children 2 through 10 years of age, routine immunization with meningococcal conjugate vaccine is recommended only for those children at continued increased risk of invasive disease, a risk that does not include out-of-home childcare.[83]

Streptococcus pneumoniae.

Incorporation of heptavalent (7-valent) pneumococcal conjugate vaccine (PCV7) into the routine childhood immunization schedule in the US in 2000 resulted in dramatic reductions of both the frequency of invasive pneumococcal disease and the frequency of PCV7-containing serotypes.[84] Universal uptake of PCV7 also was associated with a decline in national rates of outpatient visits for acute otitis media in children <2 years old.[85] Serotype 19A was among the replacement serotypes associated with invasive disease in many communities,[86] as well as in childcare.[87] In 2010, introduction of a 13-valent pneumococcal conjugate vaccine (PCV13) replaced PCV7,[88] thus resulting in further declines in invasive pneumococcal disease among all age groups[89]; vigilance for possible serotype replacement is ongoing.

Before the introduction of the PCVs, the risks of invasive pneumococcal disease, *S. pneumoniae* nasopharyngeal carriage, and carriage of antibiotic-resistant *S. pneumoniae* were increased in children attending childcare. This observation has not been fully explored in the postvaccine era. However, a French study of nasopharyngeal carriage of *S. pneumoniae* in childcare attendees found stable carriage rates, a decrease in all vaccine serotypes except 19A, and decreased antibiotic resistance from 1999 to 2012.[90] Secondary spread of *S. pneumoniae* in the childcare setting has been reported, but the risk has not been characterized.

Kingella kingae.

Kingella kingae colonizes the oropharynx and respiratory tracts of young children and has been associated with invasive disease. Multiple childcare-associated outbreaks of *K. kingae* have been reported, primarily involving osteoarticular infections; endocarditis also has been described.[91–95]

Invasive Viral Infections

Echovirus.

During an outbreak of echovirus 30 infection in children and care providers in a childcare center, and in exposed parents, infection occurred in 75% of children and 60% of adults; aseptic meningitis was more frequent in infected adults (12 in 65; 18%) than in children (2 in 79; 3%).[96] A retrospective cohort study of echovirus infections in 4 childcare centers in Germany revealed that 42% of childcare attendees, 13% of their household contacts, 5% of childcare center employees, and 2% of employees' household contacts were ill over a 31-day period. Thirteen percent (12 of 92) of childcare attendees had meningitis. This outbreak likely began among children enrolled in group childcare, with secondary cases occurring among their household contacts.[97] An association with childcare also was noted in an outbreak of echovirus 18 meningitis that occurred in a rural Missouri community with an attack rate of 1 per 1000 people; contact with childcare was noted as the most common risk factor among ill people.[98]

Parvovirus B19.

Parvovirus B19, the agent of erythema infectiosum (fifth disease), can cause arthropathy, transient aplastic crisis, persistent anemia in immunocompromised hosts, and nonimmune fetal hydrops. It spreads through contact with respiratory or oropharyngeal secretions. Serologic evidence of past infection has been reported to be 30% to 60% in adults, 15% to 60% in school-aged children, and 2% to 15% in preschool-aged children.[99] The virus is endemic among young children and has caused outbreaks of disease in the childcare setting.[100,101] In an outbreak during which more than 571 school and childcare personnel were tested serologically, the highest attack rate (31%) occurred among childcare personnel.[100] A cross-sectional study of 477 childcare staff members revealed a seroprevalence of parvovirus B19 immunoglobulin G antibodies of 70%. Seropositivity was associated with age and, among staff members <40 years of age, with length of group childcare contact.[102]

A concern exists that a previously nonimmune pregnant childcare provider could be exposed and infected during her childcare responsibilities, thus resulting in transplacental transmission leading to fetal hydrops. Estimates of the risk of fetal loss when a pregnant woman of unknown antibody status is exposed are 3% for fetal death after household exposure and 2%

after occupational exposure in a school.[103] The American Academy of Pediatrics does not recommend exclusion of pregnant women from the workplace when erythema infectiosum is occurring. This recommendation is based on low rates of adverse effects on the fetus and high community prevalence of parvovirus B19 infection. Routine infection control practices, including hand hygiene and proper disposal of used facial tissues, are recommended to prevent transmission.[104]

Cytomegalovirus.

Young childcare attendees shed cytomegalovirus (CMV) intermittently in their saliva and urine after acquisition, and they often transmit virus to other children and adults with whom they have close daily interaction. Transmission is thought to occur through direct person-to-person contact and from contaminated toys, hands of childcare providers, or classroom surfaces. Prevalence studies have shown that 10% to 70% of children <3 years of age (peak, 13 through 24 months) in childcare are shedding CMV in their urine or saliva.[105–107] Nonimmune childcare providers and mothers acquire CMV at annual rates of 8% to 20% while caring for CMV-infected children. In comparison, acquisition rates of 1% to 3% were noted among nonimmune childcare providers and mothers caring for CMV-uninfected children.[108–110] Given that care providers of young children are at increased risk of acquiring CMV, women of childbearing age should be educated about the risks of acquiring CMV, potential effects on the fetus, and methods to prevent transmission including hand hygiene after changing diapers or contact with saliva.[111]

Bloodborne Viral Pathogens

Concern about the potential for spread of bloodborne organisms in the childcare setting has focused on transmission of hepatitis B virus (HBV), hepatitis C virus (HCV), and human immunodeficiency virus (HIV). Universal immunization of infants with HBV vaccine in 1991 has reduced to negligible the potential for horizontal HBV transmission in the childcare setting. Because the highest concentrations of HBV in infected people are found in blood and blood-containing body fluids, the most common and efficient routes of transmission are through percutaneous blood exposure, by sexual exposure, and perinatally. However, high levels of HBV DNA have been detected in the saliva of hepatitis B e antigen (HBeAg)–positive children, a finding suggesting that exposure to saliva could be a means of horizontal transmission.[112] Thus, if a known hepatitis B surface antigen (HBsAg) carrier bites and breaks the skin of a hepatitis B–unimmunized child, hepatitis B immune globulin and the HBV vaccine series should be administered to the hepatitis B–unimmunized child.[113] The transmission risk of HCV infection in childcare settings is unknown. The general risk of HCV infection from percutaneous exposure to infected blood is estimated to be 10 times greater than that of HIV but less than that of HBV. Rates for percutaneous exposure to HCV-containing saliva are unknown.

No cases of HIV infection are known to have resulted from transmission of the virus in out-of-home childcare. The risk of transmission of HIV by percutaneous body fluid exposure, such as biting, is low. Complete evaluation of the source and extent of exposure should be undertaken to assess the possible risk of HIV transmission and the need for PEP.[113]

Precautions for prevention of HBV, HCV, and HIV infections should be directed toward preventing transfer of blood or secretions from person to person. Childcare providers should be educated about modes of transmission of bloodborne diseases and their prevention, and each center should have written policies for managing illnesses and common injuries, such as bite wounds.[114] Standard precautions for handling blood and blood-containing body fluids should be practiced in all childcare settings. Children known to be infected with HIV or HCV or children who are HBsAg carriers should be included in childcare activities. Decisions regarding attendance at childcare and the optimal childcare environment for these children should be made jointly by the child's physician and parents after considering the risks and benefits.

Skin Lesions

The magnitude of skin infections or infestations and the rates of occurrence in children in group childcare compared with rates in age-matched children not in group childcare are not known. The most frequently recognized non–vaccine-preventable conditions are impetigo or cellulitis caused by *Staphylococcus aureus* or GAS, pediculosis, and scabies. Other conditions with skin manifestations that occur in childcare attendees include molluscum contagiosum, head lice, ringworm, herpes simplex virus (HSV) infection, and varicella.

Molluscum Contagiosum.

Molluscum contagiosum is a benign, superficial infection of the skin caused by a poxvirus. It is manifest by the presence of small, 2- to 5-mm painless skin-colored papules with central umbilication and typically resolves spontaneously within 6 to 12 months. The virus is spread by direct contact or by fomites, and humans are the only source. Infectivity is low, but outbreaks have been reported. Keeping skin lesions covered can help to prevent transmission.

Varicella-Zoster Virus.

Since 2006, the CDC has recommended a 2-dose varicella-zoster virus (VZV) vaccination program for children, with the first dose administered at 12 through 15 months and a second dose at 4 through 6 years of age.[115] Children entering childcare or starting school should be required to have age-appropriate VZV vaccination status or other evidence of immunity to chickenpox.[116] As of January 2015, 47 states required VZV vaccination for childcare and school attendance; 1 state (Montana) requires vaccination only for childcare attendance, and 2 states (South Dakota and Ohio) require vaccination only for school attendance.[117] Unimmunized children in childcare settings are susceptible to VZV infection; most reported cases occur in children <10 years of age. Universal VZV immunization has reduced cases of clinical disease among children in group childcare.[115] However, several outbreaks of chickenpox have been reported among childcare attendees in the postvaccine era, often in the setting of inadequate vaccination coverage.[115,118–122]

Herpes Simplex Virus.

Clusters of primary HSV infections occur in children in childcare, and these infections most frequently manifest as gingivostomatitis. In a study conducted in a childcare center, restriction endonuclease analysis of HSV DNA revealed that a single strain of HSV-1 had been transmitted among children.[123] A longitudinal study of 115 childcare attendees followed from early infancy found that 37% of children had evidence of HSV-1 infection by 5 years of age based on virus isolation or seroconversion, or both. The highest incidence of infection occurred among children 1 to 2 years of age.[124] Children with severe HSV-1 infections should be excluded from childcare facilities if excess drooling and secretions are present.

Methicillin-Resistant *Staphylococcus aureus*.

The emergence of community-acquired methicillin-resistant *S. aureus* (MRSA) and its predisposition for people in crowded conditions where sharing of fomites and skin-to-skin contact occurs make childcare exposure a potential risk factor. A molecular epidemiologic study of MRSA prevalence among 104 children, 32 employees, and 17 household contacts of attendees affiliated with a university medical center's childcare facility in Texas noted an overall 7% colonization rate with MRSA. Molecular typing revealed closely related, mostly community-associated isolates from 1 employee (3%), 6 (35%) family members, and 4 (2%) environmental samples. Macrolide antibiotics and asthma medications were associated with MRSA colonization.[125] An epidemiologic study of 1163 children attending 24 childcare centers in North Carolina and Virginia found that 18% were colonized with *S. aureus* and 1% with MRSA; genotyping did not indicate classroom transmission in the 2 centers that had multiple children who were colonized with the bacterium.[126] A draining wound is a reason for exclusion of a child from a childcare setting; MRSA colonization is not.

Scabies.

Scabies is caused by a hypersensitivity reaction to the adult female mite of *Sarcoptes scabiei* subspecies *hominis*, which burrows in the upper epidermis of the skin. This infestation manifests as a pruritic, erythematous papular eruption, especially in skinfolds. Transmission occurs through prolonged close contact. Children with scabies should be excluded from childcare or school until treatment is completed, and household contacts of infected children should also be treated to prevent reinfection.[127] Prophylactic treatment for childcare providers and other contacts who have had prolonged skin-to-skin contact with an infected child should also be considered because symptoms can take 4 to 6 weeks to develop in persons who have not had a previous infection. Additionally, because transmission of crusted scabies—characterized by widespread, hyperkeratotic crusted lesions—can occur after minimal contact, treatment of all close contacts of patients with such cases is recommended.

Pediculosis.

Head lice are cosmetically unappealing, but they do not transmit disease. The incidence of pediculosis capitis (head lice) among children in childcare facilities was 0.02 per 100 child-weeks in Seattle[128] and 0.03 per child-year in San Diego.[129] Because head lice are transmitted by direct head-to-head contact, childcare centers with shared sleeping areas can facilitate transmission. Treatment of infested children and their contacts with pediculicides can be considered as control measures.[130]

Tinea Capitis.

An outbreak of tinea capitis and tinea corporis secondary to *Trichophyton tonsurans* was reported at a childcare center in the United Kingdom, with infection of 12 children and 7 staff members over a 12-month period. Control of the outbreak was accomplished through use of oral antifungal agents and antifungal shampoo, exclusion of persons with cases for a short period, removal of shared items from the center, and enhanced decontamination of fomites.[131]

Vaccine-Preventable Diseases

In the US, children should be immunized against the following 16 diseases or pathogens, unless medical contraindications exist: diphtheria, tetanus, pertussis, Hib, poliomyelitis, measles, mumps, rubella, varicella, *S. pneumoniae,* HBV, HAV, influenza, rotavirus, human papillomavirus, and meningococcal disease.[31,132] Immunization of children and childcare providers should be a priority because high rates of immunization benefit children in childcare settings and their care providers. Laws requiring age-appropriate immunizations of children attending licensed childcare programs exist in almost all states. As of January 2015, vaccine mandates for HBV were active in 41 (82%) states, for HAV in 20 (40%) states, for pneumococcus in 38 (76%) states, for varicella in 48 (96%) states, and for influenza in 4 (8%) states.[133] In a study of exemptions to immunizations, children 3 through 5 years of age with immunization exemptions were 66 times more likely to acquire measles and 17 times more likely to acquire pertussis than were age-matched immunized children.[134]

Infections Associated With Animals

Animal exposure has been associated with sporadic zoonotic infections as well as outbreaks, injuries, and allergies, most notably in children <5 years of age. The increased prevalence of infections in this age group likely reflects compromised hand hygiene resulting in transmission of pathogens from animal to child. Animal interaction can occur in locations where childcare is provided, with a resident pet or visiting animal, or in public venues where children visit, including petting zoos, aquariums, county fairs, parks, carnivals, circuses, or farms. Guidelines to reduce opportunities for transmission and infection have been developed to prevent disease transmission in many of these settings.[135,136] Inadequate hand hygiene, suboptimal supervision of children's activities following animal contact, and hand-to-mouth activities following animal contact are risk factors for infection. Organisms that have been associated with close contact with animals include *E. coli* O157:H7, Shiga toxin–producing *E. coli* (STEC), *Salmonella enterica* serotype Typhimurium, *Cryptosporidium parvum, C. jejuni,* and *G. intestinalis.* In addition to enteric infections, animal exposure can result in transmission of ectoparasites and endoparasites, *M. tuberculosis* in certain settings, and local or systemic infections as a consequence of bites, scratches, stings, and other injuries.

Contact with animals within the childcare environment should occur only where control measures are established to reduce the risk of injuries and disease. Supervision of children during animal contact, strict hand hygiene after direct animal contact or contact with animal products or environment, designation of areas for animal contact that are separate from areas in which food or drink are consumed, and disinfection and cleaning of all animal areas should be observed. Amphibians, reptiles, and weasels (ferrets and mink) should be housed in cages and not handled by children. Wild or exotic animals, nonhuman primates, mammals with a high risk of transmitting rabies, wolf-dog hybrids, aggressive wild or domestic animals, stray animals, venomous or toxin-producing spiders, insects, reptiles, and amphibians should not be permitted in the group childcare setting.[137,138]

Infectious Diseases in Adults

Parents of children who attend a childcare facility and people who provide care to these children have an increased risk of acquiring infections such as CMV, parvovirus B19, HAV, and infectious diarrhea. A retrospective cohort study of children 12 to 60 months of age attending childcare in and around Quebec City, Canada found that transmission of acute gastroenteritis and acute respiratory illness from children to their parents occurred in about 1 in every 3 episodes of infection.[139] During outbreaks of diarrhea in childcare centers, 40% of childcare providers developed diarrhea.[17] During a multicommunity outbreak of shigellosis, the overall median attack rate among employed staff members of childcare centers was 6%, with a range of 0% to 17%.[18] In outbreaks of group A *Streptococcus* and echovirus 30 infection in childcare centers, adult providers and parents were affected.[96] Similar prevalence rates of pneumococcal colonization (5% among adult employees of childcare centers with child contact and 5% among nonclinical employees at a tertiary care center) were noted in a study performed in 2003 in Galveston, Texas; these data suggest that childcare providers are not at an increased risk for pneumococcal colonization in the universal PCV era.[140] Compared with nonproviders, childcare providers have a significantly higher annual risk of at least 1 infectious disease and loss of workdays as a result of infectious disease.[141] Childcare providers should receive all immunizations routinely recommended for adults.[142]

Economic Impact of Group Childcare

Illness

The economic burden of illness associated with group childcare was estimated at $1.8 billion annually adjusted to 2015 US dollars.[143,144] Precise estimates of illness burden and methods for evaluating the effectiveness of infection control interventions are limited by the multiple challenges associated with performing such assessments.[145] Attributing an outbreak to group childcare is challenging; although these settings can promote transmission of infection, childcare attendees and staff members interact with household contacts external to the childcare arrangement, thus facilitating secondary spread. A prospective evaluation of 208 families with at least 1 childcare enrollee that was conducted from November 2000 to May 2001 in the Boston area documented 2072 viral illnesses over 105,352 person-days. Among the 834 subjects, 1683 upper respiratory tract infections and 389 gastrointestinal tract illnesses were reported during the study period, with a total mean cost of $49 per respiratory tract infection and $56 per gastrointestinal illness. Decreased parental productivity during missed days of work to care for a child who had to be withdrawn from childcare accounted for a significant proportion of the nonmedical cost.[143] Another prospective study of 381 children attending childcare centers in Sydney, Australia in 2010 found that the mean cost of an influenza-like illness was AU$626 (95% CI, AU$484–768); independent drivers of cost were both parents being employed and longer duration of illness.[146]

Prevention

Specific standards should be established for hand hygiene, maintenance of current immunization records of children and providers, exclusion policies, environmental cleaning, and appropriate handling of food and medication. In studies in which improved infection control measures were implemented and monitored, both upper respiratory tract illness and diarrhea were reduced in childcare centers that received infection control interventions.[50,147] Because asymptomatic excretion and potential for transmission precede the onset of clinical symptoms in many childcare-associated infectious diseases, strategies that involve prevention are most efficacious.

Educational sessions on health topics by healthcare professionals were found to have the most impact in simultaneous surveys of licensed childcare center directors, parents, and health providers in Boston.[148] A prospective observational study of a convenience sample of 134 childcare centers in Pennsylvania noted that suburban, nonprofit, parent-funded centers had improved health and safety practices compared with centers that were located in urban areas, received their funding through state subsidies, or were designated as for profit.[149]

Local health authorities should be notified about cases of communicable diseases involving children or care providers in the childcare setting. The American Academy of Pediatrics Healthy Child Care America Child Care & Health Partnership sets standards regarding quality early education and childcare.[150] Additional resources include information about group childcare infection rates,[151] as well as guidance for preparation of childcare programs for pandemic response.[152]

Infection prevention, including reinforcement of meticulous personal hygiene, maintenance of immunization status, and efforts to reduce environmental contamination, ensures that both childcare attendees and childcare providers reduce opportunities for exposure and transmission. Controlling clusters and outbreaks of infectious diseases in the childcare setting can involve approaches that include cohorting of functional but symptomatic children and providers to minimize exclusion and economic loss. Provider and parental familiarity with guidelines and policies developed in collaboration with public health authorities and pediatric infectious disease physicians aids in the implementation of best practices.

Infectious Diseases in Refugee and Internationally Adopted Children

Mary Allen Staat

In this chapter, the infectious disease issues of 2 groups of immigrants are discussed: refugees and internationally adopted children. Refugees are noncitizen immigrants who are unable or unwilling to return to their country of origin because of persecution or a fear of persecution.[1] Internationally adopted children are immigrants who are classified as orphans; most are not truly orphaned but have been abandoned by or separated from both parents.

Since 2004 the number of refugee arrivals to the United States has ranged from 41,094 to 74,602 per year, with 69,933 arriving in 2013.[1] Of these, 26,316 (38%) were <20 years of age, and 75% were ≥5 years of age. Although refugees came from more than 62 countries, 81% of the arriving refugees in 2013 came from just 5 countries: Iraq (28%), Burma (23%), Bhutan (13%), Somalia (11%), and Cuba (6%), with some variation in the top countries since 2004.[1]

Since 1999, more than 250,000 children have been internationally adopted in the US, with a peak of 22,990 children adopted in 2004.[2]

Since 2004, the numbers have steadily declined, with only 6574 children adopted in 2013, and a significant shift has occurred in the source countries and the ages of children adopted over this period. In 2004, 83% of adopted children came from 5 countries: China (31%), Russia (26%), Guatemala (14%), South Korea (8%), and Kazakhstan (4%), and only 14% of children were ≥5 years of age. In 2013, 82% of children adopted came from 13 countries: China (34%), Ethiopia (14%), the Ukraine (5%), Haiti (5%), Uganda (4%), Russia (4%), the Democratic Republic of the Congo (3%), South Korea (3%), Philippines (2%), Ghana (2%), Bulgaria (2%), Colombia (2%), and India (2%).[1] In 2013, 39% of children were ≥5 years of age.[2] In addition, nearly all children from China in recent years have significant medical or developmental special needs, whereas in 2004 most children adopted from China were relatively healthy.

Because refugees and internationally adopted children come from resource-limited countries, healthcare providers should be cognizant of the global prevalence of infectious diseases that are seen less commonly in native-born North Americans. Both types of immigrant groups are at increased risk for common infectious diseases such as tuberculosis (TB), intestinal parasites, dermatologic infections, and infestations. In addition, infections with hepatitis B virus (HBV), hepatitis C virus (HCV), human immunodeficiency virus (HIV), and *Treponema pallidum* (syphilis) are far more prevalent in the countries of immigrants where resources for screening and prevention are scarce compared with the US.

Refugee and internationally adopted children differ in terms of the general medical screening they receive before arrival in the U.S.[3–8] First, most refugees are subjected to organized screening evaluations, including a physical examination, before emigration visas are issued. For children >15 years of age, predeparture screening includes serologic testing for HIV and syphilis and a chest radiograph to assess for evidence of TB. In contrast, only adoptees from certain countries with high rates of TB (e.g., China and Ethiopia) have been required to undergo this organized screening procedure for TB.[5,7] Second, because medical screening for refugees usually is sponsored by responsible medical organizations, results of such testing typically are accurate. For international adoptees, results of serologic test for HIV, syphilis, and HBV from country of origin typically are provided. When tests from countries with established screening programs (e.g., China and Ethiopia) have been repeated in the US, previous results generally have proven to be accurate. However, the accuracy of testing for children from other countries is not known. Third, preventive measures such as immunizations, vitamin supplementation, and dental care are undertaken for most refugees, whereas in adoptees, preventive care is inconsistent. Finally, differences in the types of infectious diseases also may distinguish refugees from adopted children. Although both populations are susceptible to a variety of infectious agents, because the countries of origin and the existing living conditions differ, refugee children are more likely to have been exposed to infections such as typhoid fever, malaria, filariasis, flukes, or schistosomiasis, which occur less commonly in internationally adopted children from countries outside Africa.

Guidelines for Evaluation

Because of the preeminence of infectious diseases in resource-limited countries, recommendations for screening tests are weighted toward infectious disease processes, but aspects of general health, including vision, hearing, dental, developmental and mental health screenings, also should be included.[3–8] Despite the healthy appearance of many immigrant children, children should be evaluated by a healthcare professional within 2 weeks after arrival to ensure that they have been or are screened properly and receive preventive healthcare services. Table 4.1 outlines the recommended screening tests for infectious diseases for refugee and internationally adopted children. The reader also is referred to pathogen-specific chapters.

TABLE 4.1

Recommended Tests for Refugee and Internationally Adopted Children

Test	Refugee Children	Internationally Adopted Children
Tuberculin skin test (TST)	All	All[a]
Hepatitis B virus serologic testing	All	All
Hepatitis B surface antigen (HBsAg)[a]		

Hepatitis B surface antibody (anti-HBs)		
Hepatitis B core antibody (anti-HBc)		
Hepatitis C virus serologic testing	Some	Some[a]
Human immunodeficiency virus 1 and 2 serologic testing	≥15 years of age	All[a]
Syphilis serologic testing		
Nontreponemal test (RPR, VDRL, or ART)	≥15 years of age	All
Treponemal test (TPPA, MHA-TP, or FTA-ABS)	Not recommended	All
Stool examination		
Microscopic evaluation for ova and parasites (3 specimens)	All[b]	All
Giardia intestinalis and *Cryptosporidium* antigen (1 specimen)	All[b]	All
Complete blood count	All	All
Urinalysis	All	Not recommended

[a] Consider reassessing 6 months after arrival.

[b] All should be screened if no presumptive treatment occurred before arrival to the United States. See Centers for Disease Control and Prevention: http://www.cdc.gov/immigrantrefugeehealth/guidelines/domestic/intestinal-parasites-domestic.html.

ART, automated reagin test; FTA-ABS, fluorescent treponemal antibody absorption; MHA-TP, microhemagglutination-*Treponema pallidum*; RPR, rapid plasma reagin; TPPA, Treponema pallidum particle agglutination; VDRL, Venereal Disease Research Laboratory.

Hepatitis A

Virtually all inhabitants of resource-poor countries will have contracted hepatitis A virus (HAV) by early adulthood. Now that HAV vaccine is recommended for all US children ≥12 months of age,[9] immunoglobulin G (IgG) anti-HAV testing in children >1 year of age should be considered for all immigrants to determine which children should be immunized.[10] Screening for immunoglobulin M (IgM) anti-HAV can be useful to identify the child with acute HAV infection so that secondary prevention through HAV vaccine can be provided to unvaccinated family members and close contacts. Because HAV infection is anicteric in young children,[9] and because most young children are asymptomatic, the only way to identify children who may shed HAV for months is by screening with an IgM anti-HAV test. Even in the absence of jaundice, symptoms of HAV infection should prompt evaluation for viral hepatitis in recently arrived immigrants or adoptees.[9]

Hepatitis B

Routine screening for HBV infection is recommended for all refugees and internationally adopted children.[4–8] Early identification of HBV infection is important to provide appropriate management and to initiate vaccination of household contacts and caregivers. The prevalence of chronic HBV infection varies by region, and the rates of infection in refugee and internationally adopted children mirror the rates of infection in their country of origin. Children typically acquire HBV by vertical transmission, although bloodborne infection and horizontal transmission also can have occurred.[11–28] In international adoptees, the prevalence of chronic HBV infection was 20% in Romanian adoptees from the early 1990s[14–16]; however, more recent studies have consistently shown a prevalence of 1% to 5%.[17–25]

HBV screening tests, including the HBV surface antigen (HBsAg) and antibodies to surface (anti-HBs) and core (anti-HBc) antigens, are recommended in the medical evaluation of internationally adopted children and refugees.[4–8] All 3 tests should be performed to determine whether the child is immune as a result of immunization, has recovered from infection, or has acute or chronic hepatitis B. Common patterns of the hepatitis B serology profile are shown in Chapter 213. In a child who is found to be HBsAg positive, testing should be repeated 6 months later; if HBsAg persists for ≥6 months, the child has chronic hepatitis B. If the child no longer has HBsAg and has developed anti-HBs, the child had acute infection, has recovered, and is no longer able to transmit HBV to others. Children with acute or chronic HBV infection (positive HBsAg) can transmit HBV to others and should have additional tests performed, including HBV e antigen (HBeAg), HBV e antibody (HBeAb), quantitative HBV polymerase chain reaction (PCR), α-fetoprotein, and serum hepatic enzyme levels. HBsAg-positive children should be followed by a hepatologist for management. For children with negative test results initially, some experts recommend repeat testing for HBV approximately 6 months after arrival in the US to exclude infection just before arrival[8,25] In addition, children with acute or chronic HBV infection also should have serologic testing for HAV (to determine the need for vaccination) and HCV (for management and treatment considerations).

Vaccination of household contacts of children with acute or chronic HBV (HBsAg-positive children) must occur promptly. Epidemiologic studies have demonstrated that up to 20% of unvaccinated household contacts of HBV cases become HBsAg positive within ≥5 years of exposure within the home,[26,27] and transmission of HBV from newly adopted children to their parents is well documented.[26–28]

Hepatitis C

Until more is known regarding the incidence and prevalence of HCV infection in refugee and internationally adopted children, screening for this virus is not recommended routinely.[4–8] However, if the child has a history of specific risk factors such as current or former injection drug use, receipt of blood products, or residence in settings with a documented high prevalence of HCV, testing should be performed.[29] These risk factors often are difficult to ascertain in either group of children. One study reported that the prevalence of HCV antibody in internationally adopted children was <1%.[21] Recommendations may change in the near future because curative treatment is now available. Antibody testing is performed initially, and if the antibody test result is positive, HCV PCR is performed to confirm infection. Nonimmune or unimmunized children with HCV infection should be immunized for HAV and HBV and should be referred to a hepatologist for further management of HCV.

Human Immunodeficiency Virus-1 and Human Immunodeficiency Virus-2 Infection

Refugees ≥15 years of age routinely are tested for HIV before coming to the US.[5] Children <15 years of age are not tested unless they are in a high-risk situation. Otherwise, for refugee children not tested abroad, routine testing is not recommended for refugees unless indicated clinically. In contrast, most internationally adopted children have been tested for HIV-1 anti-IgG by enzyme immunoassay (EIA) in their birth country. Although reports of HIV infection in internationally adopted children are rare,[16,21] routine screening by EIA is recommended for all internationally adopted children on arrival in the US.[7,8] Positive or indeterminate results should be resolved with use of HIV DNA PCR. If clinical suspicion of HIV infection exists, HIV DNA PCR testing should be considered if the result of antibody testing by EIA is negative. Antibody retesting ≥6 months after arrival in the US should be considered.[8] Families are now permitted to adopt children with HIV infection. Thus clinicians should be prepared to provide care and resources for children arriving in the US with HIV infection.

Preadoptive testing for HIV-2 infection is not performed routinely. HIV-2 infection is prevalent in some African nations and is now recognized on several other continents; perinatal transmission appears to be limited. Symptoms suggestive of HIV infection in a child with negative EIA results for HIV-1 should prompt testing for HIV-2.

Tuberculosis

TB is highly prevalent in the countries of origin for both refugees and internationally adopted children; therefore, screening on arrival to the US is recommended for both groups.[4–8] In 2015, 66% of the 9563 persons with active TB cases in the US were foreign born.[30] The incidence in foreign-born persons (15.1 cases per 100,000) was more than 13 times the incidence among US-born persons (1.2 cases per 100,000) during 2013 to 2015.[30] In 2015, among foreign-born persons with reported TB in the US, Asians had both the highest case count (3007 cases) and the highest incidence (28.2 cases per 100,000 persons). The top 5 countries of origin for foreign-born persons with TB were Mexico (n = 1250; 19.7%), the Philippines (n = 819; 12.9%), India (n = 578; 9.1%), Vietnam (n = 513; 8.1%), and China (n = 424; 6.7%).[30] In addition, in 2014, 88% of the 91 multidrug-resistant TB cases in the US occurred in foreign-born persons. One study reported that TB rates were 32 times higher in foreign-born children and 6 times higher in US-born children with foreign-born parents compared with rates in US-born children with US-born parents.[31]

Both refugees and internationally adopted children are at increased risk for *Mycobacterium tuberculosis* infection. High proportions of immigrants and refugees are found to have latent TB infection (LTBI), with rates ranging from 20% to 76%.[32–36] One study found that 7% of immigrants had active pulmonary TB.[36] The rate of LTBI is lower in internationally adopted children compared with refugees, ranging from 14% to 21%,[37–39] and TB disease rarely has been reported.[40,41] Retesting children at least 3 months after arrival in the US has been supported by data from 2 studies, in which children with initially negative tuberculin skin test (TST) results had repeat TST >3 months later, with positive TST results in 13% to 20% of these children.[38,39]

In the past, refugees ≥15 years of age and children <15 years of age with concern about TB exposure or disease were screened with a chest radiograph before arriving in the US. If the chest radiograph findings were abnormal, microscopic evaluation of sputum or gastric aspirate for acid-fast bacilli was performed. Sputum-positive people are banned from entry into the US until sputum smears are negative. The overseas screening requirements for TB for immigrants and refugees bound for the US underwent a major revision in 2007, including TB screening for all people.[42] These requirements are still in the process of being implemented. International adoptees from certain countries with high rates of TB (China and Ethiopia) now fall under the same requirements as other immigrants and refugees.[42] For other adoptees, screening in the country of origin is performed inconsistently, and results generally are documented only in older children.

For both refugees and internationally adopted children, screening for TB should be performed at the initial assessment by placement of a TST (5 tuberculin units [TU] purified protein derivative) or interferon-γ release assay (IGRAs), such as QuantiFERON-TB Gold (Cellestis Limited, Carnegie, Australia) and T-SPOT (Oxford Immunotec, Marlborough, Mass), for children ≥5 years of age.[5–8,43] For TB disease, the sensitivity of IGRAs is reported to be comparable to that of the TST. For LTBI, IGRA specificity is higher than that of the TST, but sensitivity is not known. For immunocompetent children ≥5 years of age, IGRAs can be used in place of a TST to confirm cases of active TB or LTBI. The TST should be read 48 to 72 hours later by a healthcare professional. A reading of ≥10 mm of induration is considered positive for both refugees and internationally adopted children. A reading of ≥5 mm is considered positive if the child has known contact with a person with active TB, an abnormal chest radiograph, signs or symptoms suggestive of TB, or evidence of immunosuppression. Children with a positive TST or IGRA result should have a thorough physical examination and chest radiograph performed to assess for *M. tuberculosis* disease. If findings are normal, the diagnosis of LTBI is made, and treatment with a 9-month course of isoniazid is begun. Retesting of children ≥6 months after arrival should be considered for all children with negative test results, given the high rate of false-negative TST results shortly after arrival to the US; retesting by IGRAs has not been reported in this population of children.[38,39] A negative result on the TST or IGRA does not rule out *M. tuberculosis* infection definitively.

Although most refugees and internationally adopted children with *M. tuberculosis* infection have LTBI, disease should be considered in children with pneumonia or nonspecific symptoms such as fever, malaise, growth delay, weight loss, cough, night sweats, or chills. Pulmonary TB is the most common site of infection in children, followed by lymphatic TB. Chest radiographs can reveal hilar or mediastinal lymphadenopathy, segmental or lobar infiltrates, or pleural effusion. Cavitary lesions and miliary disease are less common. Extrapulmonary manifestations in the central nervous system, middle ear and mastoids, lymph nodes, bone, joints, and skin can be seen. Recovery of the responsible organism is paramount because many children arrive from countries in which drug-resistant *M. tuberculosis* is common. Gastric aspirates or bronchoscopy, or both, can be useful adjuncts in a child too young or too ill to expectorate sputum.[43]

Vaccination with bacille Calmette-Guérin (BCG) is common in most resource-poor countries, but it is not a contraindication to the use of a TST.[8,43] Previous studies demonstrated that TST after BCG vaccination does not elicit induration of ≥10 mm, and thus a history of BCG vaccination does not affect interpretation of the TST.[44,45]

BCG vaccination can be recognized by a 2- to 4-mm scarification, typically on the left deltoid. Occasional complications include enlargement of the regional lymph nodes or nodularity or ulceration at the vaccination site. The granuloma typically is located in the deltoid region and may or may not be draining and can be associated with regional or distant sites of infection (Fig. 4.1). Culture of the drainage yields *Mycobacterium bovis*. No consensus exists on the management of this condition. Some lesions resolve without treatment, whereas others require excision or treatment with isoniazid, erythromycin, or clarithromycin.[43,46,47]

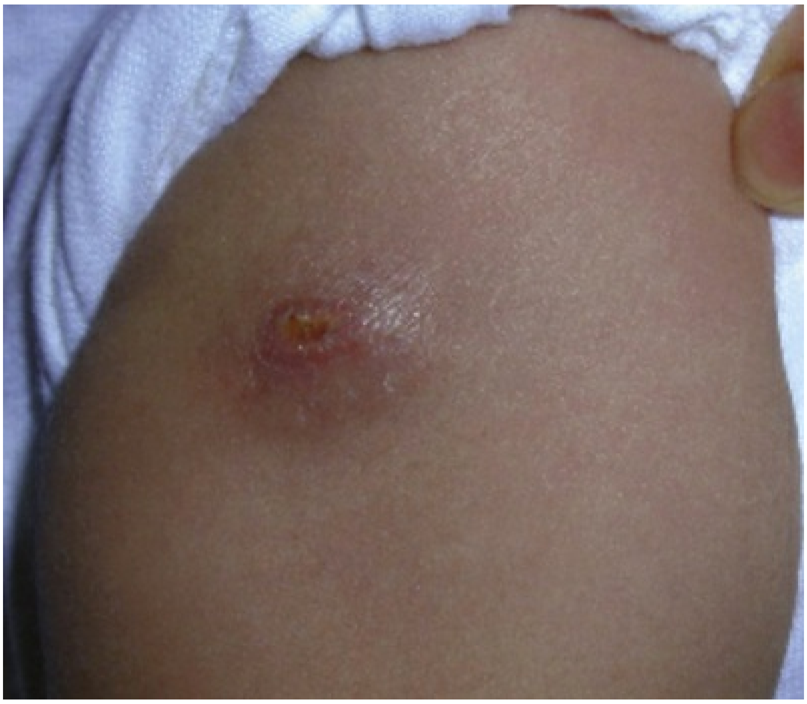

FIGURE 4.1 **Child with granuloma caused by *Mycobacterium bovis* at site of bacille Calmette-Guérin vaccination.**

Enteric Infections

Intestinal parasites are common in both refugee and internationally adopted children; infection rates vary by age and country of origin.[12–14,17–24,48–52] Although most children will not have had testing before coming to the US, presumptive treatment of refugees from certain regions of the world is recommended before departure to the US.[53] All refugees from the Middle East, South Asia, and Southeast Asia are recommended to receive albendazole for roundworm infestation and ivermectin for *Strongyloides stercoralis*. African refugees also should receive presumptive treatment for *Strongyloides,* and for refugees originating from areas endemic for schistosomiasis, treatment with praziquantel should be given. In African countries where microfilarial *Loa loa* infection is endemic, ivermectin should not be given for *Strongyloides* because treatment with ivermectin in the presence of *Loa loa* has been associated with encephalopathy; instead, a 7-day course of albendazole is given.

Additional details of country-specific recommendations, timing, dosing, and duration of treatment can be found in the Centers for Disease Control and Prevention (CDC) guidelines for refugee and immigrant care, available on the CDC website (http://www.cdc.gov/immigrantrefugeehealth/guidelines/domestic/i parasites-domestic.html).[53]

Many different parasites, both pathogenic and nonpathogenic (Table 4.2), can be seen in both groups of immigrants. Refugees compared with internationally adopted children are more likely to have nematodes and trematodes. In adoptees, the prevalence of intestinal parasites varies from 9% to 51%, depending on the child's age and country of origin; older children and children originating from countries other than Korea have higher rates.[17–24,52] One study in internationally adopted children found that the overall prevalence of intestinal parasites was 29%; 19% had *Giardia intestinalis,* and <1% had helminths.[52] A higher prevalence was found in older children, but there was no increased risk with the presence of malnutrition or gastrointestinal symptoms.[52,53] In contrast, in refugees, 17% of children had *Giardia,* whereas 19% had helminths.[51]

TABLE 4.2

Pathogenic and Nonpathogenic Intestinal Parasites

Parasite Type	Pathogens	Nonpathogens
Protozoa	*Giardia intestinalis*	*Endolimax nana*
	Entamoeba histolytica	*Entamoeba coli*
	Dientamoeba fragilis[a]	*Entamoeba gingivalis*
	Balantidium coli	*Entamoeba hartmanni*
	Blastocystis hominis[a]	*Entamoeba polecki*
	Cystoisopora belli	*Iodamoeba butschlii*
	Cryptosporidium parvum	*Chilomastix mesnili*
	Cyclospora cayentensis	*Enteromonas hominis*
	Microsporidium species	*Retortamonas intestinalis*
		Trichomonas hominis
		Trichomonas tenax
Helminths		
Nematodes (roundworms)	*Ascaris lumbricoides* (roundworm)	
	Trichuris trichiura (whipworm)	
	Strongyloides stercoralis (threadworm)	
	Enterobius vermicularis (pinworm)	
	Necator americanus (hookworm)	
	Ancyclostoma duodenale (hookworm)	
Cestodes (tapeworms)	*Hymenolepis* species	
	Taenia saginata (beef tapeworm)	

	Taenia solium (pork tapeworm)	
	Schistosoma species	

[a] Controversy exists regarding the pathogenicity of this organism.

Both refugees (who cannot be presumed to have been treated) and adoptees should be screened for intestinal parasites on arrival to the US.[5–8] The diagnosis is made by examination of preserved stool for ova and parasite testing; testing multiple specimens increases the sensitivity,[52,54,55] with a yield of 79% for 1 specimen, 92% for 2 specimens, and an additional 8% for a 3rd specimen.[52] One stool specimen also should be evaluated for *G. intestinalis* and *Cryptosporidium parvum* by using antigen testing.[8] Repeat stool samples are essential to assess the effectiveness of treatment for the identified parasite and to determine the presence of new (or newly found) pathogens. If the child remains persistently symptomatic, additional stool examinations are warranted, and testing for other parasites such as *Cyclospora* and *S. stercoralis* should be considered. In adoptees, screening for parasitosis with eosinophil counts is not indicated because most infections are caused by protozoa *(G. intestinalis)* and nonmigrating nematodes (pinworms), which do not elicit peripheral blood eosinophilia.[8] However, for either group, for children with negative stool ova and parasite examinations and eosinophilia (absolute eosinophil count exceeding 450 cells/mm^3), additional serologic testing should be done.[4,5,8] In this case, serologic testing for *S. stercoralis* should be performed, regardless of country of origin. Moreover, children with eosinophilia who are from sub-Saharan Africa, Southeast Asia, or areas of Latin America where schistosomiasis is endemic should have serologic testing for *Schistosoma* species. Similarly, testing for filariasis should be performed in children with eosinophilia who come from areas where filariasis is endemic. Because a variety of parasites can cause filariasis (see Chapter 278), if test results are positive, consultation with an infectious disease specialist with expertise in this disease is recommended to ensure that correct treatment is given.

Bacterial enteric pathogens appear to be less common than intestinal parasites in immigrants and adoptees; however, most studies have not assessed these groups systematically for bacterial causes. Children with bloody diarrhea or diarrhea associated with high fever should have stool examined for bacterial enteropathogens (e.g., *Salmonella, Shigella, Yersinia, Campylobacter*) as part of the initial evaluation.[8]

Chagas Disease (American Trypanosomiasis)

Chagas disease, caused by *Trypanosoma cruzi,* is endemic throughout much of Mexico, Central America, and South America. The risk of Chagas disease varies by region within endemic countries. Although the prevalence of Chagas disease in refugees or internationally adopted children is unknown, screening is warranted because treatment of infected children is highly effective compared with treatment in adults.[8] Serologic testing should be performed only in children ≥12 months of age because of the potential presence of maternal antibody.

Syphilis

Refugees ≥15 years of age routinely are screened for syphilis before resettlement.[5] Although refugees are not screened routinely upon arrival in the US, refugees of any age should be tested if there is clinical suspicion for syphilis or there is evidence or concern for sexual exposure.

Most internationally adopted children have documentation of syphilis screening in their birth country; syphilis rarely has been reported after arrival in the US.[17–24] In children with a history of syphilis, it often is difficult to obtain the details of the birth mother's history, treatment, and management. In addition, in children with suspected *T. pallidum* exposure, details of the evaluation and prescribed treatment regimens often are incomplete or uninterpretable. For internationally adopted children, screening with both a nontreponemal test and a treponemal test is recommended.[8] A positive treponemal test result warrants a complete and thorough evaluation to document the extent of the disease and to provide optimal treatment.

Other Testing

A complete blood count is recommended for refugees and internationally adopted children.[5–8] The hemoglobin and red blood cell indices can identify children with anemia, iron deficiency, hemoglobinopathies, or malaria. A low white blood cell count and lymphopenia can indicate HIV infection or malnutrition. Eosinophilia is common among refugees and suggests parasitic infection.[4–8,53] For refugees, a urinalysis is recommended to assess for hematuria and pyuria.[4,53] Hematuria can indicate schistosomiasis, and pyuria can reflect a urinary tract infection or renal TB. Routine screening for malaria is not recommended, but malaria should always be considered in children with fever who come from endemic areas.[5]

Elevated blood lead levels have been reported in internationally adopted children, and lead testing is recommended for all international adoptees.[56] No formal recommendation exists for refugees; however, it is likely that they could benefit from screening.

Other Infections

Dermatologic Infections.

Lice, scabies, tinea, and molluscum contagiosum are common in both refugees and internationally adopted children. The incidence of these conditions has not been well documented. The physical examination should include careful skin evaluation so that appropriate treatment is given.

Upper Respiratory Tract Infections.

Upper respiratory tract infections occur frequently in adopted children within the 1st month of arrival.[57] Because the past history of otitis media often is unknown and because many children have language delays, referral to an otolaryngologist for hearing test evaluation should be considered for children with otitis media and language delays.

Other Less Common Infections.

Clinicians should be aware of other potential diseases and clinical manifestations that can be seen in refugees and internationally adopted children. These diseases are less prevalent than those discussed and do not have readily available screening tests. In addition, some diseases (e.g., neurocysticercosis) can have long incubation periods, as long as several years. In most cases, however, the longer the interval is from arrival in the US to the development of a clinical syndrome, the less likely it is that the syndrome will be attributed to a pathogen acquired in the country of origin. Population-specific health profiles can be found on the CDC's website at www.cdc.gov/immigrantrefugeehealth/profiles/index.html.

Preventive Measures

Immunizations

Both refugees and adoptees can arrive in the US without a complete immunization record, thus making the approach to optimizing immunizations challenging. The Immigration and Nationality Act of 1996 requires immigrant visa applicants to provide proof of vaccination with receipt of at least the 1st dose of the Advisory Committee on Immunization Practices (ACIP)–recommended vaccines before entry into the US.[5,6] These regulations apply to most immigrant children entering the US; however, internationally adopted children who are ≤10 years of age can obtain an exemption from these requirements; adoptive parents are required to sign a waiver indicating their intention to comply with the ACIP immunization requirements within 30 days after the child's arrival in the US. Refugees are not required to meet immunization requirements of the Immigration and Nationality Act at the time of entry into the US but must show proof of immunization when they apply for permanent residency, typically 1 year after arrival.

Refugee Children.

If immunization documents exist, they should be reviewed and can be accepted as valid if the immunizations were provided at ages and intervals acceptable to US standards.[5–8,58,59] The clinical diagnosis of vaccine-preventable diseases may not be reliable, especially for rubella and mumps; vaccine should be given. History of varicella infection may be unavailable or unreliable in these populations; therefore, children should be immunized for varicella or have antibody testing performed.

Refugees who have no records or who have incomplete immunizations should receive vaccines at their 1st visit. Guidelines for routine and catch-up immunizations should be followed.[6,58,59] Few data are available on verifying immunization status by antibody testing in refugees; however, a study found that screening for varicella was more cost effective than providing immediate vaccine for people >5 years of age.[60]

International Adoptees.

Several studies have used antibody testing to verify the immunization status of internationally adopted children.[20–24,61–69] Results differ; some studies showed inadequate protection, whereas others found good protection. Differences in study design, laboratory methods, and definitions of protection likely account for the differences. Currently, 2 acceptable approaches are recommended to ensure that internationally adopted children are protected against vaccine-preventable diseases.[8,58,59] The 1st approach is to reinitiate immunizations regardless of documentation, and the 2nd approach is to use serologic testing to determine which immunizations are needed. Because antibody testing for a single vaccine-preventable disease may not be predictive of others, a combination of reimmunization and antibody testing can be used. Serologic testing is available for most vaccine antigens (Table 4.3). For children ≥5 months of age, testing for diphtheria, tetanus, poliomyelitis, *Haemophilus influenzae* type b (Hib), and HBV can be performed. Testing for measles, mumps, rubella, varicella, and HAV antibodies can be considered only in children ≥12 months of age because of the possible presence of maternal antibody. For varicella, testing is performed to verify whether the child had previous infection because varicella immunization is not available in most countries from which children are adopted.

TABLE 4.3

Serologic Testing Available for Verifying Immunization Status

Children ≥5 Months of Age	Children ≥12 Months of Age
Diphtheria IgG EIA	Diphtheria IgG EIA
Tetanus IgG EIA	Tetanus IgG EIA
Poliovirus serotypes 1–3 neutralizing antibody	Poliovirus serotypes 1–3 neutralizing antibody

Haemophilus influenzae type b-PRP	*Haemophilus influenzae* type b-PRP
Hepatitis B surface antibody	Hepatitis B surface antibody
	Rubeola (measles) antibody
	Mumps antibody
	Rubella antibody
	Varicella antibody
	Hepatitis A antibody

EIA, enzyme immunoassay; IgG, immunoglobulin G; PRP, polyribosylribitol phosphate antibody.

Providing care for new immigrants can be rewarding. Application of directed screening tests on arrival yields incalculable dividends for prevention and for the welfare of adoptees, refugees, and their families.

7 Antimicrobial Chemoprophylaxis
8 Protection of Travelers

5

Passive Immunization

Amanda F. Goddard, H. Cody Meissner

Passive immunization provides persons with exogenous, preformed antibodies that can prevent or treat infectious diseases. In the early 20th century, hyperimmune animal sera were produced to treat specific infections. After human plasma fractionation was developed (during World War II), immune globulin (human) (IG) became available for passive immunization. Although this development was a major breakthrough, intravenous (IV) infusion of the product was found to evoke a variety of severe adverse reactions. Therefore, the IV route of administration was precluded, and IG largely was limited to intramuscular (IM) injection. For some indications, this route was not a disadvantage. However, for treatment of a primary immunodeficiency disorder, it became clear that the volume (and hence the amount of immunoglobulin G [IgG]) that could be administered by the IM route was suboptimal. In 1981, the Food and Drug Administration (FDA) approved the first United States–licensed (human) IGIV. IGIV enables administration of large doses of IgG with minimal discomfort and to produce an immediate rise in both total plasma IgG concentration and titers of specific antibodies.

The products available for passive immunization can be grouped into 4 categories: (1) standard IG for IM administration (hepatitis A, measles, rubella); (2) hyperimmune globulins that can be administered by the IM route (hepatitis B IG [HBIG], rabies IG, tetanus IG [TIG], varicella IG) or by the IV route (cytomegalovirus [CMV], vaccinia, botulism IGs); (3) IGIV; and (4) monoclonal antibodies (mAbs) (Table 5.1). In addition, 2 antitoxins of animal origin are available for limited distribution.

TABLE 5.1

Immune Globulins Prepared From Human Plasma

Nonproprietary Name	Abbreviation
FOR INTRAMUSCULAR ADMINISTRATION	
Standard immune globulin (human)	IG
Hepatitis B immune globulin (human)	HBIG
Rabies immune globulin (human)[a]	RIG
Tetanus immune globulin (human)	TIG
Varicella-zoster immune globulin (human)[b]	VariZIG
FOR INTRAVENOUS ADMINISTRATION	
Immune globulin intravenous (human)	IGIV
Cytomegalovirus immune globulin intravenous (human)	CMV-IGIV
Botulism immune globulin intravenous (human)	BIG-IGIV
Vaccinia immune globulin intravenous (human)	VIG-IGIV
Anthrax immune globulin intravenous (human)	AIG-IGIV

[a] As much of the dose as possible should be instilled around the wound.

[b] See text.

Passive immunization is used for a variety of clinical indications, including the following: (1) treatment of a primary immunodeficiency and, in certain cases, a secondary immunodeficiency; and (2) prophylaxis against infections with specific organisms. IG is less useful for treatment of established infections. However, the use of IGIV for the treatment of various conditions that involve immune dysregulation, such as immune thrombocytopenic purpura (ITP) and Kawasaki disease, has become routine.

In the following sections, the various products and their uses are discussed. Pathogen-specific and disease-specific chapters should be consulted. An effort has been made to use nonproprietary product names as they appear in the labeling, but for brevity, abbreviations are used liberally. Emphasis is placed on FDA-approved indications (i.e., those that appear in the product package inserts). In the case of IGIV, not all products have been approved or studied for all indications (Table 5.2). Moreover, in contrast to IG for IM administration, IGIV products are produced by a variety of manufacturing processes, they use several different stabilizers and excipients, various concentrations, and physical states, and they can differ in subtle ways (e.g., IgA content).

TABLE 5.2

Available Immune Globulin Intravenous Products in the United States

Product Registered Name	Manufacturer	FDA-Approved Indication
Bivigam	Biotest Pharmaceuticals	PID
Gammaplex	Bio Products Laboratory	ITP, PID
Carimune NF	CSL Behring	ITP, PID
Privigen	CSL Behring	PID, chronic ITP
Flebogamma DIF 5%, 10%	Instituto Grifols, SA	PID
Gammagard Liquid (IV, SC)	Baxter Healthcare	PID, MMN
Gammagard S/D	Baxter Healthcare	CLL, ITP, KD, PID
Gamunex-C (IV, SC)	Grifols Therapeutics, Inc.	ITP, PID, CIDP
Octagam	Octapharma USA	PID
GamaSTAN S/D (IM)	Grifols Therapeutics, Inc.	Hepatitis A, measles, varicella prophylaxis
Vivaglobulin (SC)	CSL Behring	PID
Hizentra (SC)	CSL Behring AG	PID
HYQVIA (SC)	Baxter Healthcare	PID
WinRho SDF	Cangene	Chronic or acute ITP and HIV-immune related conditions

CIDP, chronic inflammatory demyelinating polyneuropathy; CLL, chronic lymphocytic leukemia; FDA, Food and Drug Administration; HIV, human immunodeficiency virus; IM, intramuscular; ITP, immune thrombocytopenia purpura; IV, intravenous; KD, Kawasaki disease; PID, primary immunodeficiency; MMN, multifocal motor neuropathy; SC, subcutaneous.

Immune Globulin (Human)

IG is prepared by cold alcohol fractionation of pooled human plasma. It is formulated as a 16.5% protein solution. At least 96% of the total protein is IgG, but small quantities of IgM and IgA may be present. Each lot represents the pooled plasma of at least 1000 donors to provide a wide diversity of antibodies. In practice, however, each lot represents many more donors (up to 60,000). Individual donations of the plasma, like those used as the source for all human plasma derivatives, are screened for markers of certain viruses (hepatitis B, hepatitis C, human immunodeficiency viruses 1 and 2 [HIV-1 and [HIV-2], human T-lymphotropic virus 1 and 2 [HTLV-1 and HTLV-2], West Nile virus), as well as *Trypanosoma cruzi* and *Treponema pallidum*, to minimize the potential for transmission. Other steps taken to minimize such transmission are noted at the end of this chapter.

Hepatitis A

A major use of standard IG is for postexposure prophylaxis of hepatitis A virus (HAV) in susceptible persons.[1] When injected deep into a large muscle mass within 14 days of exposure, IG is 80% to 90% effective in preventing clinical hepatitis. IG is most effective when administered early in the incubation period. When administered later in the incubation period, IG may only attenuate the severity of HAV disease expression. The usual dose is 0.02 mL/kg, given as soon as possible after exposure. For persons 12 months through 40 years of age, HAV vaccine is preferred for postexposure prophylaxis. IG is recommended for people >40 years of age because of the absence of data regarding vaccine use in adults >40 years of age and the severity of HAV infection in older adults. Children <12 months of age, immunocompromised people, people with chronic liver disease, and others who may have a diminished response to vaccine should receive IG.[2]

IG may be effective for preexposure prophylaxis in travelers to areas where HAV is prevalent. However, for travelers who are ≥1 year old and whose departure is not imminent, HAV vaccine largely has replaced IG. The dose of IG depends on the age of the traveler and the length of stay. For a child <1 year old, the dose is 0.02 mL/kg if the anticipated stay is 2 months or less and 0.06 mL/kg if longer. In older persons whose departure is imminent, the dose of IG is 0.02 mL/kg, concomitant with the first dose of vaccine, for a stay of up to 5 months, and 0.06 mL/kg, concomitant with the first dose of vaccine, for a longer stay.

For people ≥12 months of age for whom IG is given for preexposure or postexposure prophylaxis, hepatitis A vaccine is given simultaneously, at a separate site and using a separate syringe.[3]

Measles

Vaccination is the major strategy for achieving protection against measles. More than 98% of persons who receive 2 doses of measles vaccine (with the first dose administered no earlier than the first birthday and the second dose administered at least 28 days after the first dose) develop serologic evidence of immunity.[4] Nonetheless, measles postexposure prophylaxis with IG is important for children <12 months of age (for age 6 to 11 months, measles, mumps, and rubella [MMR] vaccine can be substituted for IG if within 72 hours of exposure), seronegative persons who cannot be vaccinated within 72 hours of exposure, seronegative pregnant women, and immunocompromised children who are not receiving routine immunoglobulin replacement therapy. Prophylaxis is indicated for susceptible household or hospital contacts of a case. A single dose of 0.5 mL/kg administered within 6 days of exposure may prevent or modify disease and provide temporary protection. Immunocompromised children should receive 0.5 mL/kg. In either case, no more than 15 mL should be injected, and small children should be given no more than 3 mL at any single site. Manufacturers' instructions should be consulted for maximum volume injected into a single muscle. A child who is receiving routine IgG replacement therapy is likely to have a protective concentration of measles-neutralizing antibody. If the child is ≥12 months of age, live measles vaccine should be administered approximately 6 months after IG administration if no contraindication exists. For children 6 through 11 months of age who are traveling to areas where measles is endemic, MMR vaccine (rather than IG) should be administered; this dose is not counted in the required 2-dose series at ≥12 months of age. IGIV is recommended for seronegative pregnant woman and for persons who are severely immunocompromised.[5]

Rubella

IG can be considered for prophylaxis of rubella-susceptible women who are exposed to rubella early in pregnancy. As many as 85% of infants born to mothers who are infected in the first trimester of pregnancy will have signs of congenital rubella syndrome. The IG option is recommended only for women if termination of pregnancy is declined. Limited data indicate that IM IG in a dose of 0.55 mL/kg may decrease clinically apparent infection, virus shedding, and rates of viremia in infected susceptible people. Theoretically, the reduction in viral replication may decrease the likelihood of fetal infection. The absence of clinical signs in a woman who has received IG does not guarantee that fetal infection has been prevented. Infants with congenital rubella have been born to mothers who received IG shortly after exposure.

Specific Immune Globulins for Intramuscular Administration

Specific hyperimmune IGs for IM use are IgG preparations produced from plasma that is selected by screening donations or collected from donors who have been purposefully immunized or who have received a booster. Either approach can ensure the presence of high concentrations of antibody directed against 1 or more specific antigens. The manufacturing process is essentially the same as that used to prepare IG. The protein concentration differs for individual products and may be found in the package insert. Specific products available for IM administration are listed in Table 5.1. Hyperimmune IM globulins are used to prevent hepatitis B, rabies, tetanus, and varicella-zoster virus (VZV) infection.

Hepatitis B Immune Globulin

All pregnant women should be tested for circulating hepatitis B surface antigen (HBsAg). Infants born to women who are HBsAg positive (either acutely or chronically infected with hepatitis B virus [HBV]) are at high risk of developing acute and chronic HBV infection. The HBV vaccination series accompanied by a single dose of HBIG is 85% to 95% effective in preventing HBV infection in the infant. Infants born to an HBsAg-positive mother should receive HBIG (0.5 mL) within 12 hours of birth. The first of 3 doses of HBV vaccine should be given at the same time as HBIG but at a different site.

In general, HBIG is not recommended if the mother's HBsAg status is not known, but HBV vaccination series should be begun within 12 hours of birth. Ideally, in such a case, the mother should be tested for HBsAg as soon as possible after delivery. If the test result is positive, the infant should receive 0.5 mL of HBIG IM as soon as possible (within 12 to 24 hours) and if delay is unavoidable, at least within 7 days of birth; vaccination series should be completed according to schedule. Preterm infants (<2 kg) constitute a special class. If the mother's HBsAg status is unknown and cannot be determined within 12 hours, the neonate should be given 0.5 mL of HBIG as well as vaccine, because the premature infant may respond suboptimally to HBV vaccine.

After a percutaneous (needlestick, laceration, or bite) or mucosal exposure that contains or may contain HBV, blood should be obtained from the person who was the source of the exposure (if possible) to determine his or her HBsAg status. Management of the exposed person depends on the HBsAg status of the source and the vaccination and anti-HBs response status of the exposed person. Recommended postexposure prophylaxis for different situations has been outlined by the Centers for Disease Control and Prevention (CDC).[6]

Human Rabies Immune Globulin

Rabies IG (human) (HRIG) is always used in association with rabies vaccine.[7] HRIG is administered to previously unvaccinated persons to provide rabies virus-neutralizing antibody until the patient responds to vaccination by actively producing virus-neutralizing antibodies. HRIG is administered once at the same time postexposure prophylaxis is initiated with the human rabies vaccine.[7,8]

The dose of HRIG is 20 IU/kg. If anatomically feasible, the dose should be infiltrated around the wound, and any remaining dose should be administered by the IM route at an anatomic site distant from the vaccine administration. HRIG is supplied in 2-mL (300 IU) and 10-mL (1500 IU) vials with an average potency of 150 IU/mL. Thus the contents of a 2 mL vial can be used to treat a child of up to 15 kg; for larger children, additional vials are required. A 10-mL vial is sufficient to treat a 75-kg adult and as a result is less suitable for pediatric use. However, if the smaller vials are not available, an appropriate portion can be withdrawn to treat a child. The product contains no preservative; once a vial has been entered, the contents should be administered promptly, and the remainder should be discarded.

Tetanus Immune Globulin

TIG is the oldest of the specific IGs. TIG is recommended for the treatment of tetanus and for prophylaxis in certain circumstances. Tetanus is so rare in persons whose immunization history includes at least 3 doses of tetanus toxoid that TIG is not recommended for such persons. The need for active immunization with or without passive immunization depends on the condition of the wound and the patient's immunization history. Specific guidance has been provided by the Advisory Committee on Immunization Practices.[9] Persons with wounds that are neither clean nor minor and who have had 0 to 2 previous doses of tetanus toxoid or have an uncertain history of previous doses should receive TIG, as well as diphtheria and tetanus toxoids (DT), tetanus and diphtheria toxoids (Td), diphtheria and tetanus toxoids and acellular pertussis (DTaP), or tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis (Tdap), depending on age and other needed vaccines. TIG can neutralize only unbound tetanus toxin; it cannot affect toxin bound to nerve endings. A single IM dose of 3000 to 5000 units TIG is generally recommended for treatment of children and adults, with part of the dose infiltrated around the wound (250 units is maximum used for prophylaxis). IGIV contains tetanus antitoxin and can be used if TIG is not available.

Varicella-Zoster Immune Globulin

Postexposure prophylaxis should be targeted toward patients without evidence of immunity to varicella who are at high risk for severe disease and complications and who have been exposed to and likely infected by VZV. Such persons include the following: (1) immunocompromised people; (2) nonimmune pregnant women; (3) neonates whose mothers develop signs and symptoms of varicella within 5 days before delivery to 48 hours after delivery; (4) premature infants born at 28 weeks of gestation or later who are exposed in the neonatal period and whose mothers do not have evidence of immunity; (5) premature infants born before 28 weeks of gestation or who weigh <1000 g at birth and are exposed during the neonatal period regardless of maternal history of varicella disease or vaccination (because transfer of maternal antibody may not have occurred). Significant exposure can occur through residence in the same household, close contact with a playmate, proximity to a contagious patient, or contact with a contagious visitor or hospital staff member.

In December 2012, the FDA approved VariZIG, a varicella-zoster IG preparation (Cangene Corporation, Winnipeg, Canada) for postexposure prophylaxis for persons at high risk of severe disease who lack evidence of immunity to varicella and for whom varicella vaccine is contraindicated. VariZIG is a lyophilized product and after reconstitution is administered IM. VariZIG is approved for administration as soon as possible following VZV exposure, ideally within 96 hours (4 days) for greatest effectiveness, but if it is administered within 10 days, it may result in disease attenuation. The dose is 125 U (1 vial)/10 kg body weight up to a maximum of 625 IU (5 vials). The minimum dose is 125 IU, or 62.5 IU if weight is ≤2 kg.[10]

If VariZIG cannot be obtained within 96 hours after exposure, IGIV can be given at a dose of 400 mg/kg. Although licensed IGIV preparations are known to contain varicella antibody, the titer of any specific lot is uncertain. An alternative to postexposure prophylaxis with VariZIG or IGIV is administration of oral acyclovir, which should be started 7 to 10 days after exposure and continued for a total of 7 days. This approach can be considered in immunocompetent, seronegative people with significant exposure who cannot be vaccinated. The oral acyclovir dose for adults is 800 mg given 4 times a day. If a child requires acyclovir preemptively, the dose is 40 to 80 mg/kg per day, divided into 4 doses. As an alternative, exposed immunocompetent children and adults can be given varicella vaccine within 3 to 5 days of exposure if they have not previously received 2 doses of vaccine and have no contraindication.

Immune Globulin Intravenous

(Human)

IGIV, like IG, is prepared from large pools of plasma derived from as many as 60,000 donors. The early steps in its manufacture are similar to those used for preparing IG. Further processing of individual products is performed by a variety of techniques, including steps such as polyethylene glycol precipitation, ion exchange chromatography, and exposure to low pH. This variation reflects, in part, the lack of consensus on the optimal procedure for preparing IGIV on a commercial scale in a form that is safe for IV administration. Final formulations are diverse, such as freeze-dried or in solution, different protein concentrations of the solution, different pH, and various stabilizers and other excipients that can be used in several different combinations. The product package label should be consulted for a brief synopsis of the product's preparation and properties.

Each lot of IGIV must contain minimum levels of antibodies to certain infectious organisms or toxoids (measles, poliovirus, and diphtheria). These concentrations were established to ensure lot-to-lot consistency rather than to match the clinical indications for individual products. Even though the use of large plasma pools enhances consistency, IGIV products differ in sources of plasma. As a result, antibody titers to other bacterial and viral pathogens can vary significantly among preparations and lots.[11,12] In addition, processing steps can alter functional capabilities of IgG or change the relative distribution of immunoglobulin subclasses. These changes may or may not be reflected in antibody titers measured by nonfunctional assays. In addition, individual products have undergone clinical trials for only a certain subset of indications. Even when several IGIV products carry the same indication, direct comparisons of the efficacy of multiple products in a single clinical trial are uncommon. For all these reasons, IGIV cannot be considered a uniform generic product. Available products in the US are shown in Table 5.2. Certain physiologic properties intrinsic to IGIV preparations (and variable among products) should be considered in all persons for whom administration is considered and especially in persons who have underlying conditions. Such considerations include the following: high volume load, sodium content, and osmolality, especially in neonates and young children, as well as in patients with cardiac disease, renal impairment, or thromboembolic risk; 2% to 10% carbohydrate content in children with diabetes or renal impairment; low pH in neonates; and average IgA content (<2 to 720 μg/mL) in persons with anti-IgA antibodies.

Approved Indications

Current FDA-approved available IGIV products in the US have the following 6 indications: (1) replacement therapy for primary immunodeficiency disorders associated with defects in humoral immunity; (2) treatment of ITP to induce a rapid rise in platelet count when needed to prevent or control bleeding; (3) prevention of coronary artery aneurysms associated with Kawasaki disease; (4) prevention of bacterial infections in patients with hypogammaglobulinemia associated with B-cell chronic lymphocytic leukemia; and (5) maintenance therapy to improve muscle strength in adults with multifocal motor neuropathy; (6) improvement of neuromuscular disability and maintenance therapy to prevent relapse of chronic inflammatory demyelinating polyneuropathy (Table 5.3). Previous products were approved for prevention of infection and graft-versus-host disease in adult bone marrow transplant recipients and for prevention of infection in children with HIV infection.

TABLE 5.3

Approved Indications for Immune Globulin Intravenous Therapy

Indications	Dosage	Comments
REPLACEMENT THERAPY		
Primary immunodeficiency	~400 mg/kg q4wk (average dose)	Adjust dose according to individual response
Chronic lymphocytic leukemia	400 mg/kg q3–4 wk	Cost effectiveness questioned
Bone marrow transplantation	500 mg/kg q1wk	Other anti-infective therapies also effective
Human immunodeficiency virus infection in children	400 mg/kg q2–4 wk	Useful in selected symptomatic patients
IMMUNE MODULATION		
Idiopathic thrombocytopenic purpura	400 mg/kg daily for 5 days, *or* 1 g/kg single dose	Useful in acute and chronic cases
Kawasaki disease	2 g/kg single dose	10%–20% of patients may need a second dose
Multifocal motor neuropathy	400 mg/kg daily for 5 days	Repeat doses dependent on

		clinical response
Chronic inflammatory demyelinating polyneuropathy	400 mg/kg daily for 5 days	Repeat doses dependent on clinical response

Primary Immune Deficiencies

IGIV is standard replacement therapy in primary immunodeficiency, and all IGIV products include this indication.[13] Clinical experience with IGIV in many different types of primary immunodeficiency has been favorable. Patients with the following primary immunodeficiencies have associated hypogammaglobulinemia and may benefit from replacement IGIV therapy: X-linked agammaglobulinemia, common variable immunodeficiency, severe combined immunodeficiency, hyper-IgM syndrome, congenital agammaglobulinemia, and Wiskott-Aldrich syndrome.

The objective of replacement therapy is to determine the dose and frequency that will result in freedom from serious infections. Monitoring the trough levels of IgG in parallel with the patient's clinical course has been helpful in accomplishing this objective. A range of effective doses, dosing schedules, and trough levels has been observed. The usual schedule for IGIV infusion is once every 3 or 4 weeks, and the typical dose is 400 mg/kg (range, 300 to 800 mg/kg). Trough concentrations of IgG should be maintained in the range of 400 to 500 mg/dL.[14] In 2006, IG subcutaneous (Vivaglobulin, CSL Behring) was FDA approved for people with primary immunodeficiency. It is the first subcutaneous IG approved that can be self-administered weekly (158 mg/kg) by using a portable pump, and it has gained favor for this reason.

Secondary Immune Deficiencies

Chronic lymphocytic leukemia and the immune suppression that occurs in patients undergoing bone marrow transplantation result in quantitative and qualitative humoral immunodeficiency. Although IGIV reduces infections in these conditions, unresolved issues are selection of patients most likely to benefit, optimal timing and duration of administration, and the relative effectiveness of IGIV and other anti-infective therapies.

Infection with HIV causes dysregulation of humoral immunity with impaired functional antibody activity. Some HIV-infected children have fewer bacterial infections while they are receiving IGIV; hence IGIV may benefit selected patients. With the use of combined antiretroviral therapy, antimicrobial prophylaxis (e.g., trimethoprim-sulfamethoxazole), and vaccination, the need for IGIV has decreased, but it can be considered in patients with recurrent serious bacterial infections and IgG ≤400 mg/dL or evidence of functional antibody deficiency.[15]

Immunomodulation

Mechanism of immunomodulation by IGIV and its use in treatment of inflammatory and autoimmune diseases have been reviewed.[16] Potential anti-inflammatory mechanisms include neutralization of pathologic autoantibodies, enhanced clearance of autoantibodies, inhibition of phagocytosis by effector cells, altered complement deposition, altered cytokine expression, neutralization of superantigens, and modulation of lymphocyte function.[17] Because immunomodulation does not appear as a separate category in the labeling of IGIV, the labeled indications in this category are considered individually in this discussion.

Immune Thrombocytopenic Purpura.

ITP can follow viral infections. Antibodies that are specific for or that cross-react with platelet surface antigens coat the cell surface and promote increased clearance of platelets by the spleen. In patients with ITP, IGIV can effect a rapid increase in platelet counts (often within 24 hours of infusion) and thereby avert life-threatening bleeding. One hypothesis is that IgG in IGIV interacts with phagocytic Fc receptors, thus blocking clearance of platelets and allowing them to enter or remain in the circulation[18] However, the mechanism likely is more complex.[18]

Many different IGIV products are useful for the treatment of ITP, although few direct comparisons of effectiveness exist, and no tests predict efficacy. IGIV has been studied in acute and chronic ITP in adults and children. Not all patients respond, but children do so more frequently than adults, and the increase in platelet count is more prolonged in children treated for acute ITP. Because acute ITP can resolve spontaneously, especially in young children, it is important to consult a hematologist during planning of the therapeutic approach.[19] In general the IGIV dose used is 0.8 to 1 g/kg.[20,21]

Kawasaki Disease.

Immune dysregulation may play a role in diseases for which a specific cause has not been identified. Kawasaki disease is an acute inflammatory condition with multisystem vasculitis that can result in arterial aneurysms, particularly of the coronary vessels. Several IGIV preparations have been studied for the treatment of this condition. IGIV administered concurrently with aspirin rapidly downregulates the inflammatory response. IGIV in combination with aspirin reduces the incidence of coronary artery aneurysms from 20% to 25% to <5%. IGIV should be administered within the first 10 days of illness and within 7 days of onset of symptoms if possible; a single dose of 2 g/kg infused over 10 to 12 hours is recommended.[22] Patients with Kawasaki disease that is diagnosed after 10 days of fever also should receive aspirin and IGIV promptly, although benefit has not been studied in this setting.

Children who have persistent or recrudescent symptoms may benefit from a second dose of IGIV 2 g/kg. Inasmuch as the cause of Kawasaki disease is unknown, it is possible that not all IGIV preparations (or all lots) are equally effective.[22]

Bone Marrow Transplantation.

IGIV may reduce the risk of infection in recipients of bone marrow transplants. In addition, several studies have reported IGIV to lower the incidence of acute graft-versus-host disease, but in one study this result only was observed in patients who were >20 years of age. Increased doses of IGIV have been associated with veno-occlusive disease.[23,24] A meta-analysis concluded that prophylaxis did not affect mortality rates or infection-related outcomes.[25]

Chronic Idiopathic Demyelinating Polyneuropathy and Multifocal Motor Neuropathy.

IGIV is thought to compete with pathologic autoantibodies.[26] The dose of IGIV used to treat multifocal motor neuropathy is 0.5 g/kg per day for 5 consecutive days once a month for 3 months. Subcutaneous IG has been shown to elicit a response comparable to that of IGIV.[27] In addition, chronic idiopathic demyelinating polyneuropathy can be responsive to plasma exchange and corticosteroid therapy, whereas multifocal motor neuropathy is unresponsive or even worsens.[28]

Other Uses

The number of clinical conditions for which IGIV is used exceeds its approved indications, and the off-label use of IGIV has been implicated in shortages of IGIV. This section includes some of the more frequent off-label uses of IGIV.

Toxic Shock Syndrome.

IGIV has been used an adjuvant for the treatment of toxic shock syndrome associated with staphylococcal and streptococcal disease. IGIV typically contains antibodies against superantigen toxins (including toxic shock syndrome toxin-1, staphylococcal enterotoxins, and streptococcal exotoxins) produced by both these organisms.[29] Furthermore, the anti-inflammatory properties of IGIV may help ameliorate the exaggerated cytokine response induced by superantigens. Animal studies and human case reports suggest the utility of IGIV as adjuvant therapy for the treatment of toxic shock syndrome.[30,31] The efficacy of IGIV as adjunctive therapy in streptococcal toxic shock syndrome was studied in a double-blind, placebo-controlled trial, but the trial ended prematurely because of poor patient accrual. Although statistical significance was not evident, results suggested a 3.6-fold higher mortality rate in placebo recipients. A retrospective review of streptococcal toxic shock did not show a difference in mortality rates or hospital length of stay, whereas a comparative observational study demonstrated improved survival.[32,33] Because most patients respond rapidly to fluids, vasopressor therapy, and antimicrobial therapy, some experts reserve IGIV for patients who do not respond to initial therapy. The typical dose of IGIV for this purpose is 1 g/kg given once, although a range of doses has been used.

Neonates.

Because of the high morbidity and mortality rates in preterm infants, the effects of IGIV in this population have been studied extensively.[34] Despite enthusiasm and the apparent logic of replacing missing antibodies, studies to date have shown minimal benefit, and routine use is not indicated.[34,35]

Parvovirus B19.

Most parvovirus B19 infections are mild and do not require treatment. However, anemia can be prolonged in patients with a variety of immunodeficiencies. IGIV (400 mg/kg daily for 5 days) has been reported to reduce the viral load and to restore erythropoiesis in selected patients. An alternate dosing regimen of 2 g/kg over fewer days has been used.[36,37,38] Anemia, hydrops, and persistent neonatal infection also can occur with intrauterine infection. In conjunction with intrauterine transfusions of red blood cells, IGIV may be helpful in ameliorating anemia associated with congenital parvovirus B19 infection.[37,39,40]

Immune-Mediated Cytopenias.

Patients with a variety of immune-mediated cytopenias, including anemia, thrombocytopenia, and neutropenia, have been treated with IGIV.[41,42] In autoimmune neutropenia, IGIV has been shown to cause a transient rise in neutrophil count that may be beneficial in instances of severe infection, with recombinant human granulocyte colony-stimulating factor typically used for sustaining counts.[42,43] Published reports support the use of IGIV in HIV-infected persons with ITP, although antiretroviral agents comprise the primary therapy.[44]

Guillain-Barré Syndrome.

Guillain-Barré Syndrome (GBS) is an acute, immune-mediated, inflammatory polyneuropathy. IGIV and plasma exchange represent the main methods of treatment. Large, randomized controlled trials of IGIV versus placebo in children with GBS are not available.[45,46] Results from small trials in children with GBS are consistent with data from larger randomized trials in adults, thus suggesting that IGIV therapy can shorten the time to recovery.[47] The mechanism of IGIV in GBS is uncertain.[48,49]

Specific Immune Globulins for

Intravenous Administration

Currently, 5 specific, plasma-derived hyperimmune polyclonal products for IV administration are approved for prophylaxis or therapy of infectious disease (see Table 5.1).

Cytomegalovirus Immune Globulin.

CMV-IGIV (human) is used for prophylaxis of CMV disease associated with stem cell or solid-organ transplantation, typically in conjunction with antiviral prophylaxis.[50–54] The use of CMV-IGIV for prophylaxis of CMV disease varies among transplant centers. Factors that influence the susceptibility of transplant recipients to CMV disease include organ type, immunosuppressive regimen, and the CMV status of the donor and recipient. CMV-negative transplant recipients who receive an organ from a CMV-positive donor are at highest risk for CMV disease and typically receive some form of CMV prophylaxis. CMV-IGIV for in utero CMV infection is not recommended; a randomized controlled trial showed no benefit over placebo.[55–58] Of concern in a randomized trial was that CMV-IGIV recipients had higher obstetric complications.[58]

Botulism Immune Globulin.

Botulism IGIV (human) (BIG-IV) was approved by the FDA in 2003 under the orphan drug program. It is indicated for infants <12 months of age for treatment of botulism suspected to be caused by either toxin type A or toxin type B. Produced by immunization of healthy adults, BIG-IV is available under the trade name BabyBIG, only through the California Department of Health Services (510-231-7600, all days and hours). A 5-year randomized, placebo-controlled treatment trial demonstrated the safety and efficacy of BIG-IV in reducing the mean hospital stay per case from approximately 5.5 weeks to 2.5 weeks, as well as a reduced mean hospitalization cost per case by approximately $90,000. Treatment with BIG-IV should be initiated as soon as possible to neutralize toxin and should not be delayed for laboratory confirmation of a suspected case.[59] BabyBIG is not indicated for foodborne or wound botulism. In 2013 the FDA-approved heptavalent equine botulism antitoxin (HBAT) containing antitoxin to types A, B, C, D, E, F, and

G replaced previous A, B, and E products as the only products available in the US for naturally occurring noninfant botulism; HBAT is available only through the CDC (770-488-7100 all hours and days).[60]

Vaccinia Immune Globulin.

Vaccinia IG (human) (VIG) was developed in the 1960s for ameliorating side effects associated with smallpox (vaccinia) immunization, including eczema vaccinatum, generalized vaccinia, and progressive vaccinia.[61] The original preparation contained a high proportion of protein aggregates and thus was administered by the IM route and is no longer available. Vaccinia IGIV (VIG-IV) is the only product currently available for treatment of complications of vaccinia vaccination. Supplies of VIG-IV are stored in the Strategic National Stockpile. Release of VIG-IV from the stockpile requires CDC approval.

Anthrax Immune Globulin Intravenous.

Anthrax IGIV (human) (AIG-IV) was FDA approved in March 2015 for inhalational anthrax treatment in adult and pediatric patients in combination with antibacterial drugs. It is manufactured from the plasma of persons who received anthrax vaccine. It is stored in the US Strategic National Stockpile to be available in response to an anthrax emergency.

Monoclonal Antibodies

The development of hybridoma technology in the 1970s permitted the production of essentially unlimited supplies of any mAb. The effectiveness of mAbs that either block bacterial components or modify proinflammatory cytokines has been studied in septic shock syndrome. The mAbs directed against endotoxin in the treatment of gram-negative bacillary septicemia were not beneficial.[62,63] The advantages of mAbs include the avoidance of a requirement for a large IV infusion over several hours, a predictable supply of a highly standardized product, elimination of concern about adventitious agents, and avoidance of unwanted antibody in a polyclonal product that could interfere with a live virus vaccine.[64]

Palivizumab is a humanized murine mAb directed against the surface fusion glycoprotein of respiratory syncytial virus. After monthly IM administration of palivizumab, the risk of hospitalization for respiratory syncytial virus infection among high-risk infants was reduced from 10.6% among placebo recipients to 4.8% among prophylaxis recipients.[65] Guidance for use of palivizumab prophylaxis provided by the American Academy of Pediatrics has become increasingly restrictive based on data published since licensure in 1998 that now indicate little benefit from monthly prophylaxis for infants and young children at increased risk of hospitalization.[66]

Raxibacumab is a recombinant human IgG1λ mAb that binds and neutralizes the free protective antigen (PA) component of *Bacillus anthracis* toxin. Antibiotics aid in controlling infection, but they do not clear toxins present in the bloodstream. The effectiveness of raxibacumab is based on animal models (rabbits and monkeys) of inhalational anthrax. This is the first mAb approved using the FDA Animal Efficacy Rule (well-controlled animal studies when human studies are not ethical of feasible). Guidance is available for management of pediatric systemic illness.[67] Currently, anthrax IG or raxibacumab antitoxin is indicated in patients with anthrax systemic disease. Raxibacumab is also approved for prophylaxis of inhalational anthrax if other alternatives are not available or are contraindicated. Because inhalational anthrax is a possible bioterrorist threat, doses of raxibacumab are stored in the US Strategic National Stockpile.

Immunoglobulin Products Prepared From Animal Plasma

In the past, several approved animal-derived immunoglobulin products were available for treating various infectious agents or their toxins. Few of these agents are in use currently. Most have been supplanted by analogues of human origin (e.g., RIG, TIG) or by other therapeutic modalities. The only available products in this category are botulism antitoxin and diphtheria antitoxin. They can be obtained from the CDC for emergency use in the treatment of foodborne botulism and diphtheria, respectively. These equine immunoglobulin products are provided only when specifically indicated. Because immediate anaphylaxis and delayed serum sickness are possible adverse reactions, these products should be used only when their lifesaving potential outweighs their risks. Procedures for skin testing and desensitization are readily available, and the physician should always be prepared to treat any adverse event.[68]

Adverse Reactions to Immune Globulins Prepared From Human Plasma

The most common adverse reaction to IM-administered IGs is pain at the injection site. Local or facial flushing can occur, as can headache, chills, or nausea, but these symptoms are less common. Severe systemic reactions are rare.

Infusion-Related Reactions

Reactions such as fever, headache, myalgia, chills, nausea, and vomiting often are related to the rate of IGIV infusion and usually are mild to moderate and self-limited (Box 5.1). These reactions may result from formation of IgG aggregates during manufacture or storage. Product-to-product variations in adverse effects may occur among individual patients. An isoimmune hemolytic reaction has been described rarely, especially if large doses of IGIV are infused. Less common but severe reactions include the following: hypersensitivity and anaphylactoid reactions marked by flushing, changes in blood pressure, and tachycardia; thromboembolic events; aseptic meningitis; and renal insufficiency. The causes of these reactions are unknown. The incidence of adverse events often can be decreased by following the package insert for the individual product with regard to the rate of administration. Aseptic meningitis associated with pleocytosis can occur, especially among patients receiving high doses of IGIV (2 g/kg).[69] Acute renal failure has been reported rarely following IGIV infusions, particularly among patients with preexisting renal disease who receive IGIV products containing sucrose.

Box 5.1

Adverse Effects of Immune Globulin Intravenous Therapy

Minor Systemic Reactions

Headache, back or hip pain, fever, dizziness or lightheadedness, nausea, flushing

Pyrogenic Reactions

High fever and systemic symptoms

Vasomotor or Cardiovascular Manifestations

Changes in blood pressure and heart rate

Infrequent, Serious Reactions

Aseptic meningitis[a]

Acute renal failure

Hypersensitivity reactions[b]

Anaphylaxis

---

[a] Aseptic meningitis may be more common in adults or children with specific underlying conditions.

[b] Reaction reports are more common for products that contain sucrose.

Anaphylactic reactions induced by anti-IgA can occur in patients with primary antibody deficiency who have a total absence of circulating IgA and who develop IgG antibodies to IgA. IgE anti-IgA is less common.[70,71] These reactions are rare in patients with panhypogammaglobulinemia and are more common in patients with selective IgA deficiency and subclass IgG deficiencies. In the rare instances in which reactions related to anti-IgA antibodies have occurred, use of IgA-depleted IGIV preparations may decrease the likelihood of further reactions. Because of the rarity of these reactions, screening for IgA deficiency and anti-IgA antibodies is not recommended routinely.

Interference With Active Immunization

Antibodies present in IGs can interfere with the immune response to vaccines. Provided the 2 products are administered with separate syringes at different sites, this is rarely a problem when the vaccine is an inactive substance such as a toxoid, a polysaccharide, or a killed virus preparation, even when the vaccine is given simultaneously with the IG. However, antibodies in IG can interfere with viral replication after administration of live virus vaccines and thus can prevent successful immunization. The effect on the immune response to measles immunization has been demonstrated, but in principle, similar interference could occur with any live virus vaccine. Measles, mumps, rubella, or varicella vaccine should not be given in the 2 weeks before or 3 months after a patient receives any IgG preparation or whole or fractionated blood. Because high doses of IGIV can inhibit the response to measles vaccine for extended periods, longer intervals are required as the IGIV dose is increased (up to 11 months after 2 g/kg IGIV as for Kawasaki disease) to provide sufficient time for passively acquired antibodies to wane.[72]

Transmission of Infectious Agents

Although IGs prepared from human plasma are biologic products and hence must always be considered to carry a theoretic risk for transmission of viruses, they have a remarkable record of safety. Even IGIV, which is administered directly into the bloodstream, often in large quantities, has been extremely safe. Investigations have revealed no documented case of transmission of hepatitis by US-licensed IGs for IM use. Similarly, no evidence indicates transmission of HIV by US-licensed IGs for either IM or IV administration.[73,74]

Several cases of non-A, non-B hepatitis were associated with IGIV administration between 1983 and 1987.[75] These cases involved sources of IGIV that were not commercial lots available in the US.

In February 1994, however, a worldwide recall of US-licensed IGIV products manufactured by Baxter Healthcare Corporation was initiated because of hepatitis C virus transmissions.[76] Cases of hepatitis C occurred in several countries, including the US, among persons who received these products between April 1, 1993, and February 23, 1994, after which they were removed from the market.[77]

Concern regarding the potential transmission of prion disease by IG products has been raised. These concerns are highlighted by the lack of serologic assays to screen blood products for prions. The findings of several studies suggested that the likelihood of prion transmission through plasma products is exceedingly small. These findings include the observations that very low levels of prions are found in the plasma of affected persons and that the processing of plasma for the production of IGs typically inactivates prions.[78,79] To date, no case of prion disease has been linked to IG therapy.

Laboratory studies have shown that many manufacturing steps that are intrinsic to the process of preparing IgG greatly lower viral and prion burden. For example, alcohol fractionation of plasma partitions virus and prions away from the IgG fraction.[80] If the alcohol concentration at a particular manufacturing step is sufficiently high and the virus is sufficiently labile (e.g., HIV), alcohol is viricidal.[80] Other precipitating agents, such as polyethylene glycol, can achieve similar partitioning of viruses. Incubation at low pH, either in the presence or absence of enzymes, has a strong antiviral effect.[81,82]

Solvent-detergent treatment has been added to purification procedures to enhance viral inactivation in various IGs. This treatment destroys enveloped viruses such as HBV, hepatitis C virus, and HIV.[83] Another viral inactivation step used for some products is heat treatment, which can be performed in the presence of stabilizers to prevent denaturation of the IgG.[84] Purification processes now include nanofiltration, that is, filtration of the product through membranes with pore dimensions that permit the passage of proteins but not viruses.

Product Shortages

Periodic shortages of certain IGIV products have occurred, for multiple reasons. In some cases, production problems have occurred. Increased use of IGIV is another contributing factor. Use of IGIV in the US has increased by approximately 10% each year, and production has not kept pace. Off-label use of IGIV contributes to shortages. A study of 12 academic health centers revealed that 52% of IGIV prescribed was used for off-label indications.[85] In response to these shortages, some hospitals have developed committees to review and restrict use of IGIV.

The Future

In the future, new IGIV products as well as additional mAbs are likely to become available. Several mAbs have been licensed for use for noninfectious indications, including those for the following: (1) organ transplantation (through inhibition of cytokine activity or depletion of lymphocyte subsets); (2) treatment of malignant diseases (i.e., lymphoma, colon cancer, and breast cancer); and (3) immunologic modulation (i.e., asthma and Crohn disease). The mAbs used for the treatment and prevention of infectious diseases in clinical development include the following: *Clostridium difficile, Staphylococcus aureus*, HIV, rabies virus, West Nile virus, Shiga toxin–producing *Escherichia coli,* and *Candida albicans.*[86,87] Multiple other mAbs are being studied for the prevention and treatment of infection.[86,88–91] Other advances include alterations to extend the half-life of palivizumab.[87,89] The Ebola epidemic demonstrated the benefit of rapid development of mAbs.[92,93]

Active Immunization

Raymond A. Strikas, Alison C. Mawle, Larry K. Pickering, Walter A. Orenstein

Vaccines are among the most effective means of preventing disease, disability, and death. The use of vaccines, initiated by Jenner in 1796 with demonstration that inoculation of material from cowpox lesions could prevent smallpox, predates the germ theory of disease. The profound impact of vaccines on disease incidence is a result of both the availability of safe and effective vaccines and effective strategies and programs to deliver vaccines to target groups. Eradication of smallpox in 1977, one of the greatest public health achievements, required both disease surveillance and containment with a highly effective vaccine.[1] Similarly, global efforts to eradicate poliomyelitis involve comprehensive disease control strategies, including national and multicountry mass vaccination campaigns, intensive surveillance for wild poliovirus, and house-to-house vaccination programs. These programs have succeeded in terminating transmission of wild poliovirus in the Americas, the Western Pacific, Europe and Southeast Asia, and gains are being made in the remaining endemic countries of Pakistan, Afghanistan, and Nigeria (www.polioeradication.org).[2–4] Efforts to reduce or even eliminate measles and neonatal tetanus, 2 of the major causes of childhood fatality worldwide, also are progressing, although cases of measles continue to occur worldwide.[5,6] Gavi, the vaccine alliance, a collaboration among organizations in the public and private sectors, provides support for introduction of vaccines in the world's poorest countries (≤$1580 per capita income per year) that previously could not support their use. (www.gavi.org).

Benefits of successful vaccines include not only reductions in disease incidence, disability, pain, and suffering, but also savings in healthcare costs in both the economically developed and developing world. Studies in the United States have reaffirmed benefits of childhood immunization.[7–8] A cost-benefit analysis covering vaccine-preventable diseases of childhood, including diphtheria, tetanus, pertussis, poliomyelitis, hepatitis A, hepatitis B, *Haemophilus influenzae* type b (Hib) infection, measles, mumps, rubella, rotavirus infection, pneumococcal disease, and varicella, estimated that routine childhood immunization among members of the 2009 US birth cohort will prevent approximately 42,000 early deaths and 20 million cases of disease, with net savings of $13.5 billion in direct costs and $68.8 billion in total societal costs, respectively.[7]

Immunization and Vaccines: Overview

Immunization is the process of artificially inducing immunity or providing protection from disease. *Active immunization* is the process of stimulating the body to produce antibody and other immune responses (e.g., cell-mediated immunity) through administration of a vaccine or toxoid. *Passive immunization* is provision of temporary immunity by administration of preformed antibodies derived from humans or animals (see Chapter 5).

Vaccine Content

Biologic agents used to induce active immunization include vaccines and toxoids. Traditionally, a *vaccine* is defined as a suspension of live (usually attenuated) or inactivated microorganisms, or fractions thereof, which is administered to induce immunity and prevent infectious disease or its sequelae; efforts to develop vaccines to increase immune response to cancers or to treat diseases including diabetes mellitus necessitate rethinking of this definition. *Live, attenuated* vaccines traditionally have been developed by means of serial passage (in culture or animals) of an initially pathogenic bacteria or virus strain with selection for strains that are less pathogenic for humans but that induce protective immunity (e.g., measles, mumps, and rubella

[MMR] vaccine). Live, attenuated vaccines also can be developed with use of reassortants of attenuated animal or human virus strains with virus coat antigens from pathogenic strains (e.g., cold-adapted influenza, rotavirus vaccine). *Inactivated* vaccines can consist of the following: (1) whole organisms inactivated by heat, formalin, or other agents (e.g., polio, hepatitis A, rabies vaccines); (2) purified protein (e.g., acellular pertussis, influenza, and meningococcal serogroup B vaccines) or polysaccharide antigens (e.g., pneumococcal, meningococcal, and intramuscular typhoid vaccines) from whole organisms; (3) purified antigens produced by genetically altered organisms (e.g., hepatitis B and human papillomavirus [HPV] vaccines produced by yeast); or (4) chemically modified antigens, such as polysaccharides conjugated to carrier proteins to increase immune response (e.g., conjugated Hib, pneumococcal, and meningococcal vaccines). *Toxoids* are bacterial toxins produced in bacterial culture that have been rendered nontoxic but retain the ability to stimulate formation of antitoxin.

Vaccine and toxoid preparations also contain other constituents intended to enhance immunogenicity and stability but that can be responsible for adverse reactions.[9] Such constituents include the following: (1) suspending fluid, which can be saline or complex fluids containing constituents derived from the biologic system or medium in which the vaccine is produced (e.g., egg or serum proteins); (2) preservatives, stabilizers, or antimicrobial agents, which are used to inhibit bacterial growth in viral cultures or the final product or to stabilize antigens (e.g., mercurials, phenols, albumin, glycine, neomycin); and (3) adjuvants, which enhance response to inactivated antigens (e.g., aluminum phosphate, aluminum hydroxide, amorphous aluminum hydroxyphosphate sulfate and monophosphoryl lipid A [ASO_4]). Concern about the possibility of adverse effects from cumulative exposure to mercury in the environment has led to removal of thimerosal as a preservative from most US vaccines recommended for infants.[10] The only vaccines administered to infants that contain thimerosal as a preservative are some influenza vaccines (multidose vials) and diphtheria-tetanus (DT) vaccine. Physicians should be knowledgeable about the constituents of each vaccine, which are described in vaccine information package inserts.

Vaccine Development, Licensure, and Approval

Immunologic Basis of Response to Vaccines

The 2 major approaches to active immunization are (1) live, attenuated vaccines and (2) inactivated or detoxified agents or their purified components. For some diseases, such as poliomyelitis and influenza, both approaches have been used.

Live, attenuated vaccines have the advantage of producing a complex immunologic response simulating natural infection. Because replication of the organism and processing of antigens mimic those of the natural pathogen, both humoral and cell-mediated responses can be generated to a variety of antigens. Generally, immunity induced by a single dose of a live, attenuated vaccine is long-lasting, possibly lifelong. However, the strength of response, particularly the humoral response, usually is less robust than the response following natural infection, and detectable antibodies can wane with time, resulting in some potential loss of protection. Induction of immunity by live vaccines can be inhibited by passive antibody, whether from transplacental acquisition from the mother or receipt of immunoglobulin-containing blood products. Thus optimal response depends on ensuring that passive antibody levels have declined (e.g., primary measles vaccination at 12 months of age instead of earlier, delay of measles vaccination after administration of blood products). In addition, because response may be only 90% to 95% after a single dose, a 2-dose or multiple-dose regimen can be necessary to induce higher levels of protection in the community and prevent spread of disease if the population is exposed (community protection).

Inactivated or purified antigen vaccines induce response only to components present in the vaccine. Generally, multiple doses, usually 3 or more, are necessary to induce satisfactory antibody levels that persist for long periods of time; booster doses at longer intervals (e.g., 10 or more years for tetanus and diphtheria toxoids) sometimes are required to ensure lasting protection. The nature of vaccine responses depends on antigen type. Protein and glycoprotein antigens usually induce both humoral immunity and memory (response through helper T lymphocytes) after multiple doses, as evidenced by more rapid, broad, and intense (anamnestic) response to successive doses. Polysaccharide antigens by themselves induce only humoral antibody without T-lymphocyte stimulation and fail to induce an anamnestic response with repeated antigenic challenge. This limitation can be overcome by conjugation of polysaccharides to protein carriers to induce both a stronger immune response in younger children and immunologic memory.

Immune Response to Active Immunization

The general mechanism by which a long-term protective memory immune response is induced requires activation of T lymphocytes by antigen-presenting cells, which then provide help to B lymphocytes to develop into antibody-producing plasma cells (i.e., T-lymphocyte–dependent response).[11,12] Polysaccharide antigens bypass T-lymphocyte help (i.e., T-lymphocyte–independent response) and induce B-lymphocyte differentiation directly, but they do not induce immunologic memory. Initiation of a T-lymphocyte–dependent antibody response occurs by activation of naïve CD4$^+$ helper T lymphocytes in response to antigen-presenting cells, generally dendritic cells. This interaction occurs through recognition of the major histocompatibility complex (MHC) on the antigen-presenting cells by the T-lymphocyte receptor and by secretion of cytokines that are necessary for maturation of naïve CD4$^+$ helper T lymphocytes to differentiate toward a helper T-lymphocyte 1 (Th1) or Th2 response.[13] Th1 responses are predominantly cell mediated, whereas Th2 responses are predominantly humoral. In the presence of interleukin-12 (IL-12), Th1 response is differentiated and is associated with secretion of IL-2 and interferon γ (IFNγ). In the presence of IL-4, Th2 response is differentiated and is associated with secretion of IL-4 and IL-5. These 2 cytokines are essential for differentiation and maturation of B lymphocytes into antibody-secreting plasma cells. A small subset of CD4$^+$ T lymphocytes does not differentiate into effector cells; instead, these T lymphocytes mature to become long-lived memory cells, which form the nucleus of the secondary immune response on reexposure to antigen. The overall response is regulated by a further class of CD4+ T lymphocytes (Treg).[14]

In a primary response, naïve B lymphocytes recognize a specific antigenic epitope on native antigen through the immunoglobulin receptor on their surface, and they differentiate into antibody-secreting cells in response to help from CD4+ Th2 lymphocytes. A given B lymphocyte is activated by a T lymphocyte responding to the same antigen. B-lymphocyte proliferation and maturation then occur in a clonal manner, and during this process, immunoglobulin (Ig) class switching (from IgM to IgG and IgA) and affinity maturation also occur. Antigen-specific plasma cells develop and secrete large amounts of clonal antibody.

The polyclonal response to a given immunogen reflects the sum of the multiple individual clonal B-lymphocyte responses that make up an antibody response. A few activated B lymphocytes mature into long-lived memory B lymphocytes, which form the basis of the rapid secondary response on the next encounter with antigen. Some plasma cells acquire the capacity to migrate toward long-term survival niches mostly located within the bone marrow, from where they may produce antibodies during extended periods.[15,16] The duration of antibody responses reflects the number or quality, or both, of long-lived plasma cells generated by immunization.[16] The mechanism of maintenance of these lymphocytes is an area of active research because the ability to mount a strong secondary response after many years is a critical component of the adaptive immune response.

Initiation of the specific immune response to a pathogen depends on the innate immune response, which is rapid, does not exhibit memory, and historically has been considered nonspecific. However, discovery of germline-encoded pattern recognition receptors has led to an understanding that specific molecular structures are recognized by pathogen-associated molecular patterns. These specific structures include toll-like receptors (TLRs), which are membrane associated, and nucleotide-binding oligomerization domain (NOD)-like receptors, which are found in the cytoplasm and include the NALP family of receptors (member of the nucleotide-binding domain and leucine-rich repeat containing gene family) and others, all of which contribute to immune activation by inducing proinflammatory cytokines, which in turn modulate the adaptive immune response. TLRs and NOD-like receptors are found on antigen-presenting cells and recognize a wide variety of molecules commonly found in pathogens. TLR4 binds lipopolysaccharide, and TLR5 binds flagellin, both common bacterial components. The NALP3 inflammasome is activated by aluminum and has been shown to be the pathway through which aluminum adjuvants enhance immunogenicity.[17]

Antibodies produced in response to immunization can mediate protection by a variety of extracellular mechanisms including (1) direct neutralization of bacterial toxin, (2) facilitation of intracellular digestion of bacteria by phagocytes (opsonization), (3) initiation of or combination with the complement pathway to cause lysis, or (4) sensitization of macrophages to promote phagocytosis. Antibodies cannot readily reach the intracellular space, which is the site of viral and some bacterial replication. However, antibodies are effective against many viral diseases by interacting with a virus before initial intracellular penetration occurs (neutralization) and by preventing locally replicating virus from disseminating from the site of entry to an important target organ, as in spread of poliovirus from the gut to the central nervous system or spread of rabies from a puncture wound to peripheral neural tissue. Antigen-specific cytotoxic T-lymphocyte–mediated responses are important components of the response to viral infections.[12]

The cell-mediated immune response also has an innate and memory effector arm. Natural killer (NK) cells recognize virally infected cells in a nonspecific manner, without generation of memory. Activated NK cells secrete a variety of soluble mediators, including IFNs that kill virus-infected cells and ILs that modulate differentiation and response of $CD4^+$ helper T lymphocytes. Cytotoxic $CD8^+$ T lymphocytes require the help of $CD4^+$ T lymphocytes (generally Th1) to differentiate and mature. $CD8^+$ cytotoxic T lymphocytes are an important part of the immune response to intracellular bacteria and viruses.[12] As viruses replicate in a cell, viral proteins are processed and presented on the cell surface as an MHC class I/peptide complex. The complex is recognized by cytotoxic T lymphocytes. As with $CD4^+$ T lymphocytes, a small subset develops into long-lived memory $CD8^+$ T lymphocytes capable of rapid reactivation as part of a secondary immune response.

Rarely, vaccination can result in immune responses that alter the course of natural infection detrimentally. For example, killed measles vaccine, a formalin-inactivated vaccine administered to some children in the United States from 1963 to 1967, sensitized some vaccine recipients so that when exposed to wild virus, they developed an atypical infection with enhanced severity of disease. The prevailing theory has been that failure of formalin-inactivated vaccine to produce response to the measles virus fusion protein led to altered immune response and atypical disease on subsequent challenge. More recent theories suggest that killed measles virus failed to induce high-avidity antibody, and immune-complex deposition was the major determinant of atypical measles.[18]

Following primary immunization with inactivated antigens, antibody response develops in 2 to 6 weeks but can be incomplete even after 2 doses; after effective priming, booster responses occur within 4 to 14 days. The initial response usually is IgM antibodies, followed within weeks by IgG antibodies. Response to live vaccines requires 1 incubation period, followed by several weeks to months for development of a strong immune response. Response to measles vaccination usually is maximal by 6 weeks, but in younger children, antibody levels can continue to rise for several months. However, protection against measles begins much earlier, and some evidence suggests that disease can be prevented even when vaccine is administered within 72 hours of exposure.

Determinants of Response

Vaccine immunogenicity and response are determined by characteristics of the vaccine and the host. Vaccine dose, presence of an adjuvant, route and site of administration, timing of doses, and vaccine handling can affect response. Vaccine doses are adjusted before licensure to ensure a high level of response (generally >90% of subjects); adjuvants permit a better response with a lower dose of inactivated antigen. The routes of administration (e.g., intradermal, subcutaneous, intramuscular, and mucosal) can determine the strength and nature of the immune response. Mucosal administration (intranasal or oral) stimulates higher levels of mucosal IgA antibodies that can inhibit disease transmission with greater effectiveness than parenteral administration, which induces limited or no mucosal response.[19] Intradermal vaccination with lower antigen doses can induce antibody responses similar to responses induced by intramuscular or subcutaneous administration of recommended doses, but intradermal vaccine is more difficult to deliver precisely and, in practice, achieves less predictable responses.

Sites of Administration

Intramuscular injections should be given in the anterior thigh (infants and toddlers) or deltoid muscle (children and adults); injection into the buttocks can produce lower antibody response, which has been documented for hepatitis B and rabies vaccines in adults, probably as a result of delivery of vaccine into adipose tissue.[20,21] Vaccines with adjuvants should be given in deep muscle because subcutaneous or intradermal injection can induce local inflammation, granuloma formation, or necrosis.[22] Timing of doses of killed vaccines is important; a minimal interval of 1 month between primary doses is usual,[8] as is delay of a 4th or reinforcing dose for 10 months or longer after the first dose to enhance response and duration of antibody persistence. The recommended routes and sites of administration and timing of doses are devised to ensure optimal effectiveness in disease prevention and should be used.

Host Factors

Intrinsic factors in the host that affect immune response include genetic factors, age, nutritional or disease status, primary or secondary immunodeficiency, sex, pregnancy, and smoking.[11,23–26] Although genetic factors such as MHC polymorphism are known to affect both cellular and humoral immune response at a molecular level for some vaccines, the precise mechanisms are unknown.[23–26] Evaluating how host genetic markers alter vaccine response could identify differences that predict successful or adverse vaccine outcome. Studies of the expression of genetic information modified on a molecular level can reveal how environmental influences affect innate and adaptive immune responses.[26] This work, combined with system vaccinologic approaches, may lead to better understanding of these immune responses.[11,12,27] Age is an important factor in response to immunization.[12] With killed vaccines, neonates generally do not develop as brisk a response as older infants or children (e.g., hepatitis B), and with certain vaccines, too early immunization can result in poor response or development of tolerance or interference (diphtheria and tetanus toxoids and acellular pertussis [DTaP]; inactivated poliovirus vaccine [IPV]; Hib conjugates). For live (and some killed) vaccines, inhibition of response by maternal antibodies determines the optimal timing for vaccination in early childhood (measles, hepatitis A). Generally, response to all vaccines is excellent in young children, adolescents, and young adults but diminishes with increasing age.[12] In adults, smoking decreases response to hepatitis B vaccine.[20,22] Extreme debilitation, primary or secondary immunodeficiency disorders (including diseases or treatments that cause immunosuppression), and some chronic diseases (renal disease, diabetes mellitus) can diminish immune response. For people with such conditions, inactivated vaccines can be recommended, although higher or more frequent doses may be required; live vaccines often are contraindicated because of the risk of disseminated disease and possible death caused by the vaccine organism.[22,28]

Measurement of Response

Ideally, reliable laboratory tests should be available to measure the presence and strength of each of the major effectors of protection against the disease for which the vaccination is administered. In routine practice, many different tests are available to assess the presence, absence, and level of antibodies. These include enzyme immunoassay (EIA), complement fixation, and immunofluorescent techniques. Assays for functional antibody, such as neutralization or opsonophagocytosis, generally are performed in reference or research laboratories, as are tests for T-lymphocyte function. $CD4^+$ Th1 and Th2 lymphocytes and $CD8^+$ lymphocytes generally are characterized by their cytokine profiles by using assays such as enzyme-linked immunospot (ELISpot) or intracellular cytoplasmic staining.

For certain diseases, such as hepatitis B, poliovirus, rubella, and measles, reliable tests exist, and antibody levels that correlate with protection are known. For some diseases, such as pertussis and HPV infection, no serologic correlate of protection has been defined. Development of improved laboratory methods to measure protection and to permit rapid diagnosis of acute disease continues to be a priority of vaccine-preventable disease control programs.

Vaccine Licensure and Approval

Before US Food and Drug Administration (FDA) licensure, a new vaccine generally requires 10 to 15 years of preclinical testing and clinical trials. Before testing a vaccine in humans, a manufacturer files an investigational new drug (IND) application with the FDA, followed by 3 phases of clinical trials that are performed to study vaccine safety, immunogenicity, and efficacy.[29,30] On completion of the prelicensure clinical trials, the following steps generally occur for a vaccine to become available and used: (1) the manufacturer applies for a Biologics Licensure Application (BLA) with the FDA; (2) the FDA licenses the vaccine; (3) the Advisory Committee on Immunization Practices (ACIP) of the Centers for Disease Control and Prevention (CDC) and the American Academy of Pediatrics (AAP)[31] and other professional medical societies make recommendations for use of the vaccine; and (4) financing is secured for the public and private sectors (Fig. 6.1).

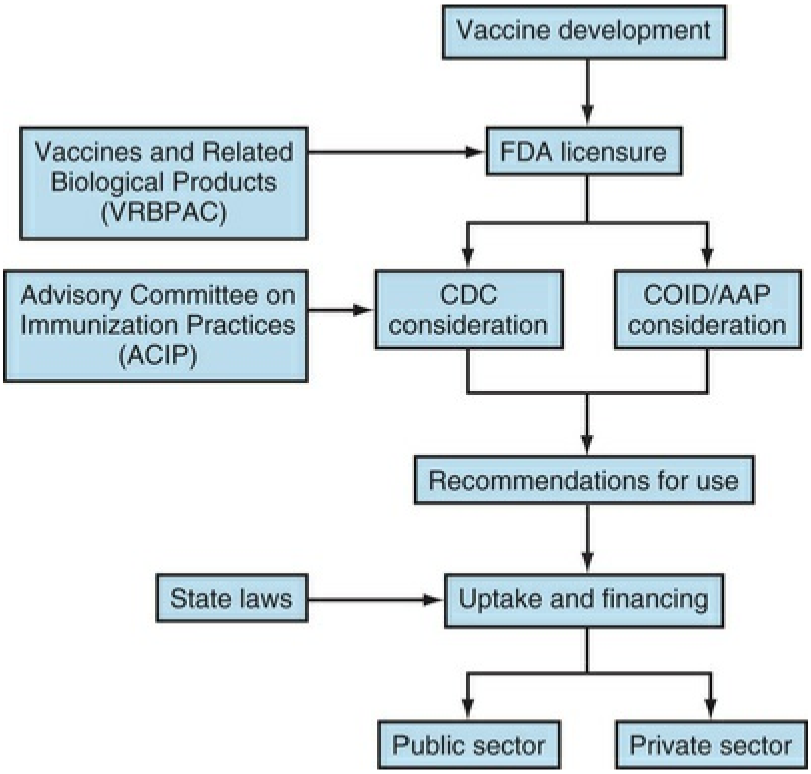

FIGURE 6.1 **Development of pediatric vaccine recommendations and policies. AAP, American Academy of Pediatrics Board of Directors; CDC, Centers for Disease Control and Prevention; COID, Committee on Infectious Diseases; FDA, Food and Drug Administration; VRBPAC, Vaccines and Related Biological Products Advisory Committee.** (Redrawn from Pickering LK, Orenstein WA. Development of pediatric vaccine recommendations and policies. Semin Pediatr Infect Dis 2002;13:148–154.)

Following FDA licensure of a new vaccine, information about the vaccine is reviewed by the ACIP. ACIP consists of 15 voting, nongovernment members appointed by the US Department of Health and Human Services for 4-year terms. In addition, many professional medical and public health societies and organizations and industry representatives participate in ACIP discussions, but they do not vote. To formulate recommendations, the ACIP establishes subject-specific work groups to review and synthesize data months to years before presentation to the ACIP, where votes are taken on vaccine use. Data considered in making recommendations are subjected to the GRADE process (http://www.cdc.gov/vaccines/acip/recs/grade/index.html). ACIP recommendations are not official until approved by the CDC director and published in the *Morbidity and Mortality Weekly Report (MMWR)* (http://www.cdc.gov/vaccines/acip/committee/charter.html) Given that new vaccines and updated recommendations appear often, the reader is advised to follow the ACIP website for new recommendations at http://www.cdc.gov/vaccines/hcp/acip-recs/vacc-specific/index.html.

Following vaccine licensure, monitoring for rare adverse events continues for some vaccines through formal phase IV trials conducted by the manufacturer, which often are required and monitored by the FDA. In addition, postmarketing surveillance for adverse events is performed and permits detection of new or unanticipated adverse events. Physician and manufacturer reporting of certain adverse events observed after vaccine administration is required by the National Childhood Vaccine Injury Act for vaccines covered under the Vaccine Injury Compensation Program.[32] The importance of postmarketing surveillance was demonstrated following licensure and wide use of tetravalent rhesus rotavirus vaccine in the US for infants in 1999. Surveillance of adverse events detected cases of intussusception within 1 week after receipt of the first or second doses of the rhesus rotavirus vaccine. Follow-up studies determined that risk of intussusception was 1 case per 10,000 doses of vaccine administered.[33] Subsequently, the vaccine was withdrawn from distribution, and recommendation for universal use in infants in the US was withdrawn.

Principles of Immunization Programs

Disease Reduction

Childhood immunization programs have reduced substantially the occurrence of vaccine-preventable diseases in the US (Table 6.1).[34–37] Declines exceed 95% for all diseases for which universal vaccination has been well implemented, with the exception of hepatitis B, which remains a common clinical disease in adults not reached by universal vaccine programs, and pertussis.[38,39] Smallpox has been eradicated, poliomyelitis resulting from indigenous wild poliovirus has not occurred since 1979 in the US, and endemic rubella has been declared eliminated in the US.[40,41] Fewer than 10 cases each of diphtheria and tetanus in children are now reported each year, and indigenous transmission of measles has been interrupted. Wide use of Hib conjugate vaccines has reduced Hib disease by >98% in the

US and in some European countries.[42–44] Use of pneumococcal conjugate vaccines (PCVs) has led to marked reductions in invasive pneumococcal disease (IPD) among vaccinated children as well as unvaccinated young infants, adolescents, and adults.[44–47] Building on the success of the program to date, the US Public Health Service established 2010 goals to eliminate indigenous transmission of measles, rubella and congenital rubella syndrome, mumps, diphtheria, poliomyelitis, Hib disease in children <5 years of age, and tetanus in people <35 years of age, and to reduce hepatitis B in people 2 to 18 years old by 90%.[48] These goals were achieved for diphtheria, measles, rubella, congenital rubella, poliomyelitis, and hepatitis B. The new Healthy People 2020 objectives include specific goals for the vaccination of adolescents, including the following: 1 dose of tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine (Tdap); 1 dose of meningococcal conjugate vaccine (MCV); 3 doses of HPV vaccine; and ≥2 doses of varicella vaccine (http://www.healthypeople.gov/2020/topics-objectives/topic/immunization-and-infectious-diseases/objectives).[48]

TABLE 6.1

Reported Morbidity of Selected Vaccine-Preventable Diseases and Vaccine Coverage Levels: United States, 20th Century and 2015

Disease	United States, 20th-Century Annual Morbidity[a]	United States, 2015 Morbidity[b]	Vaccine Coverage Levels, 2015 %[c]	Healthy People 2020 Coverage Level Goals (%)	Reduction in Morbidity (%)
Diphtheria	21,053	0	85 (≥4 doses)	90	100
Tetanus	580	25	85 (≥4 doses)	90	96
Pertussis	200,752	18,166	85 (≥4 doses)	90	90.6
Poliomyelitis (paralytic)	16,316	0	94[d] (≥3 doses)	90	100
Measles	530,217	189	92 (≥1 dose)	90	99.8
Mumps	162,344	1,057	92 (≥1 dose)	90	99.3
Congenital rubella	152	1	92 (≥1 dose)	90	99.9
Acquired rubella	47,745	5	92 (≥1 dose)	90	99.9
Haemophilus influenzae type b and unknown; <5 years of age	20,000	23[e]	94 (≥2 or 3 doses, depending on brand)	90	99.9
Varicella	4,085,120	8,370	92 (≥1 dose)	90	99.8

[e] Haemophilus influenzae type b (Hib) < 5 years of age.

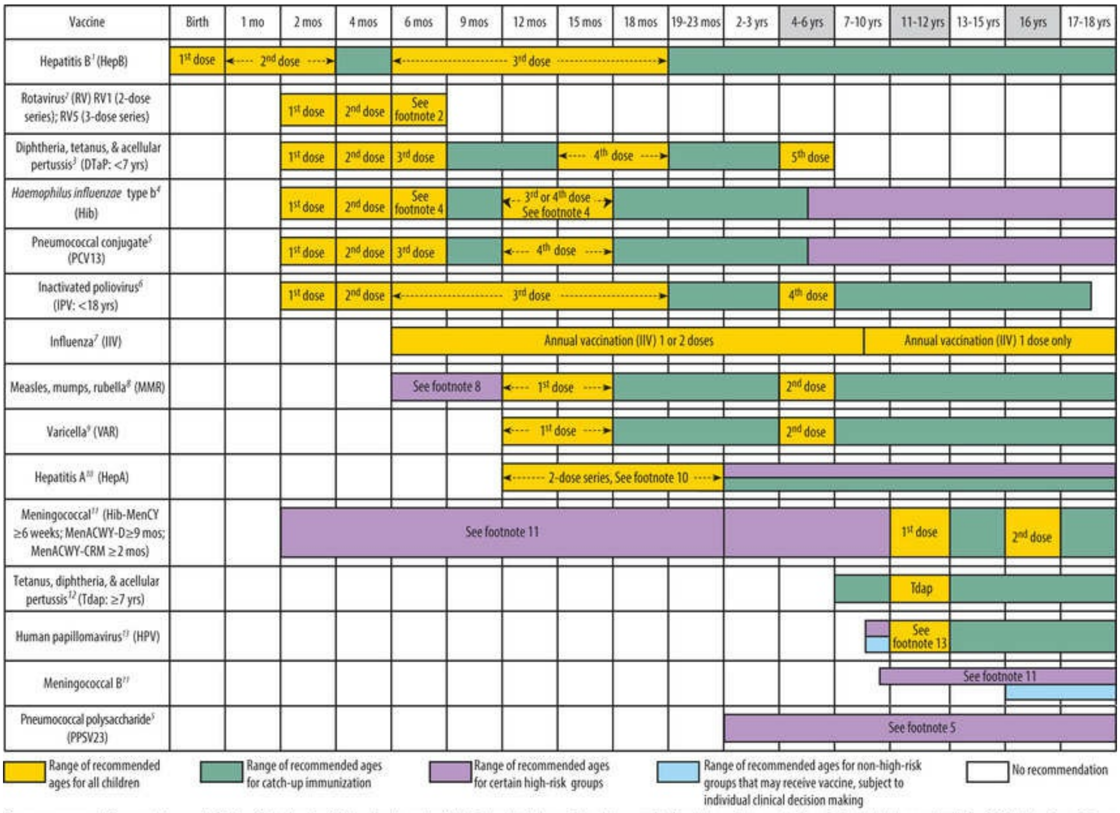
Immunization Coverage

Immunization coverage among preschool children has increased steadily after the measles resurgence that began in 1989 and stimulated unprecedented efforts to improve delivery of immunization. In 2014, coverage with 3 doses of DTaP, poliovirus, and hepatitis B virus (HBV) vaccines and 1 dose of MMR and varicella vaccines among children 19 through 35 months of age each reached or exceeded 91%.[49] Among school-aged children, coverage with the recommended series of DTaP and 2 doses of varicella and MMR vaccines exceeded 93% in 2014 and 2015, likely as a result of enforcement of comprehensive state immunization laws requiring receipt of specified vaccines for school attendance.[50] School laws often expand to include newly recommended vaccines.[51] In 2014, 87% of adolescents received 1 dose of Tdap, 79% received 1 dose of MCV4, and 40% of adolescent girls and 22% of adolescent boys received 3 doses of HPV vaccine.[52]

Vaccine Administration

Vaccine Schedules

The CDC, AAP, American Academy of Family Physicians (AAFP), and American College of Obstetricians and Gynecologists (ACOG) annually publish harmonized childhood and adolescent immunization schedules.[8] The ACIP, AAFP, ACOG, American College of Nurse Midwives (ACNM), and American College of Physicians also publish an annual adult immunization schedule (www.cdc.gov/vaccines).[53] The ACIP, with input from many liaison organizations, periodically reviews the schedules to ensure consistency with new vaccine developments and policies. The first harmonized childhood immunization schedule was published in 1995 and recommended 6 vaccines containing antigens against 9 infectious diseases.[54] Since November 2010, vaccines have been recommended universally in the childhood and adolescent immunization schedule to protect against 16 infectious diseases (Figs. 6.2 to 6.4). The harmonized schedule specifies the recommended and acceptable timing for each dose of universally recommended vaccine and for vaccines recommended for children and adolescents in selected high-risk populations.



Vaccine	Birth	1 mo	2 mos	4 mos	6 mos	9 mos	12 mos	15 mos	18 mos	19-23 mos	2-3 yrs	4-6 yrs	7-10 yrs	11-12 yrs	13-15 yrs	16 yrs	17-18 yrs

🟨 Range of recommended ages for all children

🟩 Range of recommended ages for catch-up immunization

🟪 Range of recommended ages for certain high-risk groups

🟦 Range of recommended ages for non-high-risk groups that may receive vaccine, subject to individual clinical decision making

☐ No recommendation

These recommendations must be read with the footnotes that follow. For those who fall behind or start late, provide catch-up vaccination at the earliest opportunity as indicated by the *green bars* in Fig. 6.2. To determine minimum intervals between doses, see the catch-up schedule (Fig. 6.3). School entry and adolescent vaccine age groups are shaded in *gray*.

Footnotes — Recommended Immunization Schedule for Children and Adolescents Aged 18 Years or Younger, UNITED STATES, 2017

For further guidance on the use of the vaccines mentioned below, see: www.cdc.gov/vaccines/hcp/acip-recs/index.html.
For vaccine recommendations for persons 19 years of age and older, see the Adult Immunization Schedule.

Additional information

- For contraindications and precautions to use of a vaccine and for additional information regarding that vaccine, vaccination providers should consult the ACIP General Recommendations on Immunization and the relevant ACIP statement, available online at www.cdc.gov/vaccines/hcp/acip-recs/index.html.
- For purposes of calculating intervals between doses, 4 weeks = 28 days. Intervals of 4 months or greater are determined by calendar months.
- Vaccine doses administered ≤ 4 days before the minimum interval are considered valid. Doses of any vaccine administered ≥ 5 days earlier than the minimum interval or minimum age should not be counted as valid doses and should be repeated as age-appropriate. The repeat dose should be spaced after the invalid dose by the recommended minimum interval. For further details, see Table 1, *Recommended and minimum ages and intervals between vaccine doses, in MMWR, General Recommendations on Immunization and Reports / Vol. 60 / No. 2,* available online at www.cdc.gov/mmwr/pdf/rr/rr6002.pdf.
- Information on travel vaccine requirements and recommendations is available at wwwnc.cdc.gov/travel/.
- For vaccination of persons with primary and secondary immunodeficiencies, see Table 13, *Vaccination of persons with primary and secondary immunodeficiencies,* in *General Recommendations on Immunization* (ACIP), available at www.cdc.gov/mmwr/pdf/rr/rr6002.pdf.; and Immunization in Special Clinical Circumstances, (American Academy of Pedatrics). In: Kimberlin DW, Brady MT, Jackson MA, Long SS, eds. *Red Book: 2015 report of the Committee on Infectious Diseases. 30th ed.* Elk Grove Village, IL: American Academy of Pediatrics, 2015:68-107.
- The National Vaccine Injury Compensation Program (VICP) is a no-fault alternative to the traditional legal system for resolving vaccine injury petitions. Created by the National Childhood Vaccine Injury Act of 1986, it provides compensation to people found to be injured by certain vaccines. All vaccines within the recommended childhood immunization schedule are covered by VICP except for pneumococcal polysaccharide vaccine (PPSV). For more information; see www.hrsa.gov/vaccinecompensation/index.html.

1. **Hepatitis B (HepB) vaccine. (Minimum age: birth)**
   Routine vaccination:
   At birth:
   - Monovalent hepatitis B vaccine should be administered within 24 hours of birth for medically stable infants weighing ≥ 2000 g born to hepatitis B surface antigen (HBsAg)-negative mothers.
   - Preterm infants weighing <2000 g born to HBsAg-negative mothers should receive the first dose of vaccine 1 month after birth or at hospital discharge.
   - For infants born to hepatitis B surface antigen (HBsAg)-positive mothers, administer HepB vaccine and 0.5 mL of hepatitis B immune globulin (HBIG) within 12 hours of birth. These infants should be tested for HBsAg and antibody to HBsAg (anti-HBs) at age 9 through 12 months (preferably at the next well-child visit) or 1 to 2 months after completion of the HepB series if the series was delayed.
   - If mother's HBsAg status is unknown, within 12 hours of birth, administer HepB vaccine regardless of birth weight. For infants weighing less than 2,000 grams, administer HBIG in addition to HepB vaccine within 12 hours of birth. Determine mother's HBsAg status as soon as possible and, if mother is HBsAg-positive, also administer HBIG to infants weighing 2,000 grams or more as soon as possible, but no later than age 7 days.

   Doses following the birth dose:
   - The second dose should be administered at age 1 or 2 months. Monovalent HepB vaccine should be used for doses administered before age 6 weeks.
   - Infants who did not receive a birth dose should receive 3 doses of a HepB-containing vaccine on a schedule of 0, 1 to 2 months, and 6 months, starting as soon as feasible (see Fig. 6.3).
   - Administer the second dose 1 to 2 months after the first dose (minimum interval of 4 weeks); administer the third dose at least 8 weeks after the second dose AND at least 16 weeks after the **first** dose. The final (third or fourth) dose in the HepB vaccine series should be administered **no earlier than age 24 weeks**.
   - Administration of a total of 4 doses of HepB vaccine is permitted when a combination vaccine containing HepB is administered after the birth dose.

   Catch-up vaccination:
   - Unvaccinated persons should complete a 3-dose series.
   - A 2-dose series (doses separated by at least 4 months) of adult formulation Recombivax HB is licensed for use in children aged 11 through 15 years.
   - For other catch-up guidance, see Fig. 6.3.
2. **Rotavirus (RV) vaccines. (Minimum age: 6 weeks for both RV1 [Rotarix] and RV5 [RotaTeq])**
   Routine vaccination:
   Administer a series of RV vaccine to all infants as follows:
      1. If Rotarix is used, administer a 2-dose series at ages 2 and 4 months.
      2. If RotaTeq is used, administer a 3-dose series at ages 2, 4, and 6 months.
      3. If any dose in the series was RotaTeq or vaccine product is unknown for any dose in the series, a total of 3 doses of RV vaccine should be administered.

   Catch-up vaccination:
   - The maximum age for the first dose in the series is 14 weeks, 6 days; vaccination should not be initiated for infants aged 15 weeks, 0 days, or older.
   - The maximum age for the final dose in the series is 8 months, 0 days.
   - For other catch-up guidance, see Fig. 6.3.

For further guidance on the use of the vaccines mentioned below, see: www.cdc.gov/vaccines/hcp/acip-recs/index.html.

3. **Diphtheria and tetanus toxoids and acellular pertussis (DTaP) vaccine. (Minimum age: 6 weeks. Exception: DTaP-IPV [Kinrix, Quadracel]: 4 years)**

   Routine vaccination:
   - Administer a 5-dose series of DTaP vaccine at ages 2, 4, 6, 15 through 18 months, and 4 through 6 years. The fourth dose may be administered as early as age 12 months, provided at least 6 months have elapsed since the third dose.
   - Inadvertent administration of fourth DTaP dose early: If the fourth dose of DTaP was administered at least 4 months after the third dose of DTaP and the child was 12 months of age or older, it does not need to be repeated.

   Catch-up vaccination:
   - The fifth dose of DTaP vaccine is not necessary if the fourth dose was administered at age 4 years or older.
   - For other catch-up guidance, see Fig. 6.3.

4. ***Haemophilus influenzae* type b (Hib) conjugate vaccine. (Minimum age: 6 weeks for PRP-T [ActHIB, DTaP-IPV/Hib (Pentacel), Hiberix, and Hib-MenCY (MenHibrix)], PRP-OMP [PedvaxHIB])**

   Routine vaccination:
   - Administer a 2- or 3-dose Hib vaccine primary series and a booster dose (dose 3 or 4, depending on vaccine used in primary series) at age 12 through 15 months to complete a full Hib vaccine series.
   - The primary series with ActHIB, MenHibrix, Hiberix, or Pentacel consists of 3 doses and should be administered at ages 2, 4, and 6 months. The primary series with PedvaxHIB consists of 2 doses and should be administered at ages 2 and 4 months; a dose at age 6 months is not indicated.
   - One booster dose (dose 3 or 4, depending on vaccine used in primary series) of any Hib vaccine should be administered at age 12 through 15 months.
   - For recommendations on the use of MenHibrix in patients at increased risk for meningococcal disease, refer to the meningococcal vaccine footnotes and also to *MMWR* February 28, 2014 / 63(RR01):1–13, available at www.cdc.gov/mmwr/PDF/rr/rr6301.pdf.

   Catch-up vaccination:
   - If dose 1 was administered at ages 12 through 14 months, administer a second (final) dose at least 8 weeks after dose 1, regardless of Hib vaccine used in the primary series.
   - If both doses were PRP-OMP (PedvaxHIB or COMVAX) and were administered before the first birthday, the third (and final) dose should be administered at age 12 through 59 months and at least 8 weeks after the second dose.
   - If the first dose was administered at age 7 through 11 months, administer the second dose at least 4 weeks later and a third (and final) dose at age 12 through 15 months or 8 weeks after second dose, whichever is later.
   - If first dose is administered before the first birthday and second dose administered at younger than 15 months, a third (and final) dose should be administered 8 weeks later.
   - For unvaccinated children aged 15–59 months, administer only 1 dose.
   - For other catch-up guidance, see Fig. 6.3. For catch-up guidance related to MenHibrix, see the meningococcal vaccine footnotes and also *MMWR* February 28, 2014 / 63(RR01):1-13, available at www.cdc.gov/mmwr/PDF/rr/rr6301.pdf.

   Vaccination of persons with high-risk conditions:

   Children aged 12 through 59 months who are at increased risk for Hib disease, including chemotherapy recipients and those with anatomic or functional asplenia (including sickle cell disease), human immunodeficiency virus (HIV) infection, immunoglobulin deficiency, or early component complement deficiency, who have received either no doses or only 1 dose of Hib vaccine before 12 months of age, should receive 2 additional doses of Hib vaccine, 8 weeks apart; children who received 2 or more doses of Hib vaccine before 12 months of age should receive 1 additional dose.
   - For patients younger than age 5 years undergoing chemotherapy or radiation treatment who received a Hib vaccine dose(s) within 14 days of starting therapy or during therapy, repeat the dose(s) at least 3 months following therapy completion.
   - Recipients of hematopoietic stem cell transplant (HSCT) should be revaccinated with a 3-dose regimen of Hib vaccine starting 6 to 12 months after successful transplant, regardless of vaccination history; doses should be administered at least 4 weeks apart.
   - A single dose of any Hib-containing vaccine should be administered to unimmunized* children and adolescents 15 months of age and older undergoing an elective splenectomy; if possible, vaccine should be administered at least 14 days before procedure.
   - Hib vaccine is not routinely recommended for patients 5 years or older. However, 1 dose of Hib vaccine should be administered to unimmunized* persons aged 5 years or older who have anatomic or functional asplenia (including sickle cell disease) and unimmunized* persons 5 through 18 years of age with HIV infection.

   ** Patients who have not received a primary series and booster dose or at least 1 dose of Hib vaccine after 14 months of age are considered unimmunized.*

5. **Pneumococcal vaccines. (Minimum age: 6 weeks for PCV13, 2 years for PPSV23)**

   Routine vaccination with PCV13:
   - Administer a 4-dose series of PCV13 at ages 2, 4, and 6 months and at age 12 through 15 months.

   Catch-up vaccination with PCV13:
   - Administer 1 dose of PCV13 to all healthy children aged 24 through 59 months who are not completely vaccinated for their age.
   - For other catch-up guidance, see Fig. 6.3.

   Vaccination of persons with high-risk conditions with PCV13 and PPSV23:
   - All recommended PCV13 doses should be administered prior to PPSV23 vaccination if possible.
   - For children aged 2 through 5 years with any of the following conditions: chronic heart disease (particularly cyanotic congenital heart disease and cardiac failure); chronic lung disease (including asthma if treated with high-dose oral corticosteroid therapy); diabetes mellitus; cerebrospinal fluid leak; cochlear implant; sickle cell disease and other hemoglobinopathies; anatomic or functional asplenia; HIV infection; chronic renal failure; nephrotic syndrome; diseases associated with treatment with immunosuppressive drugs or radiation therapy, including malignant neoplasms, leukemias, lymphomas, and Hodgkin disease; solid organ transplantation; or congenital immunodeficiency:
     1. Administer 1 dose of PCV13 if any incomplete schedule of 3 doses of PCV13 was received previously.
     2. Administer 2 doses of PCV13 at least 8 weeks apart if unvaccinated or any incomplete schedule of fewer than 3 doses of PCV13 was received previously.
     3. The minimum interval between doses of PCV13 is 8 weeks.
     4. For children with no history of PPSV23 vaccination, administer PPSV23 at least 8 weeks after the most recent dose of PCV13.
   - For children aged 6 through 18 years who have cerebrospinal fluid leak; cochlear implant; sickle cell disease and other hemoglobinopathies; anatomic or functional asplenia; congenital or acquired immunodeficiencies; HIV infection; chronic renal failure; nephrotic syndrome; diseases associated with treatment with immunosuppressive drugs or radiation therapy, including malignant neoplasms, leukemias, lymphomas, and Hodgkin disease; generalized malignancy; solid organ transplantation; or multiple myeloma:
     1. If neither PCV13 nor PPSV23 has been received previously, administer 1 dose of PCV13 now and 1 dose of PPSV23 at least 8 weeks later.
     2. If PCV13 has been received previously but PPSV23 has not, administer 1 dose of PPSV23 at least 8 weeks after the most recent dose of PCV13.
     3. If PPSV23 has been received but PCV13 has not, administer 1 dose of PCV13 at least 8 weeks after the most recent dose of PPSV23.
   - For children aged 6 through 18 years with chronic heart disease (particularly cyanotic congenital heart disease and cardiac failure), chronic lung disease (including asthma if treated with high-dose oral corticosteroid therapy), diabetes mellitus, alcoholism, or chronic liver disease, who have not received PPSV23, administer 1 dose of PPSV23. If PCV13 has been received previously, then PPSV23 should be administered at least 8 weeks after any prior PCV13 dose.
   - A single revaccination with PPSV23 should be administered 5 years after the first dose to children with sickle cell disease or other hemoglobinopathies; anatomic or functional asplenia; congenital or acquired immunodeficiencies; HIV infection; chronic renal failure; nephrotic syndrome; diseases associated with treatment with immunosuppressive drugs or radiation therapy, including malignant neoplasms, leukemias, lymphomas, and Hodgkin disease; generalized malignancy; solid organ transplantation; or multiple myeloma.

6. **Inactivated poliovirus vaccine (IPV). (Minimum age: 6 weeks)**

   Routine vaccination:
   - Administer a 4-dose series of IPV at ages 2, 4, 6 through 18 months, and 4 through 6 years. The final dose in the series should be administered on or after the fourth birthday and at least 6 months after the previous dose.

   Catch-up vaccination:
   - In the first 6 months of life, minimum age and minimum intervals are only recommended if the person is at risk of imminent exposure to circulating poliovirus (i.e., travel to a polio-endemic region or during an outbreak).
   - If 4 or more doses are administered before age 4 years, an additional dose should be administered at age 4 through 6 years and at least 6 months after the previous dose.
   - A fourth dose is not necessary if the third dose was administered at age 4 years or older and at least 6 months after the previous dose.
   - If both OPV and IPV were administered as part of a series, a total of 4 doses should be administered, regardless of the child's current age. If only OPV was administered, and all doses were given prior to 4 years of age, 1 dose of IPV should be given at 4 years or older, at least 6 months after the last OPV dose.
   - IPV is not routinely recommended for U.S. residents aged 18 years or older.
   - For other catch-up guidance, see Fig. 6.3.

7. **Influenza vaccines. (Minimum age: 6 months for inactivated influenza vaccine [IIV], 18 years for recombinant influenza vaccine [RIV])**

   Routine vaccination:
   - Administer influenza vaccine annually to all children beginning at age 6 months. For the 2016–17 season, use of live attenuated influenza vaccine (LAIV) is not recommended.

   For children aged 6 months through 8 years:
   - For the 2016–17 season, administer 2 doses (separated by at least 4 weeks) to children who are receiving influenza vaccine for the first time or who have not previously received ≥2 doses of trivalent or quadrivalent influenza vaccine before July 1, 2016. For additional guidance, follow dosing guidelines in the 2016–17 ACIP influenza vaccine recommendations (see *MMWR* August 26, 2016;65(5):1-54 , available at www.cdc.gov/mmwr/volumes/65/rr/pdfs/rr6505.pdf).
   - For the 2017–18 season, follow dosing guidelines in the 2017–18 ACIP influenza vaccine recommendations.

   For persons aged 9 years and older:
   - Administer 1 dose.

8. **Measles, mumps, and rubella (MMR) vaccine. (Minimum age: 12 months for routine vaccination)**

   Routine vaccination:
   - Administer a 2-dose series of MMR vaccine at ages 12 through 15 months and 4 through 6 years. The second dose may be administered before age 4 years, provided at least 4 weeks have elapsed since the first dose.
   - Administer 1 dose of MMR vaccine to infants aged 6 through 11 months before departure from the United States for international travel. These children should be revaccinated with 2 doses of MMR vaccine, the first at age 12 through 15 months (12 months if the child remains in an area where disease risk is high), and the second dose at least 4 weeks later.
   - Administer 2 doses of MMR vaccine to children aged 12 months and older before departure from the United States for international travel. The first dose should be administered on or after age 12 months and the second dose at least 4 weeks later.

   Catch-up vaccination:
   - Ensure that all school-aged children and adolescents have had 2 doses of MMR vaccine; the minimum interval between the 2 doses is 4 weeks.

9. **Varicella (VAR) vaccine. (Minimum age: 12 months)**

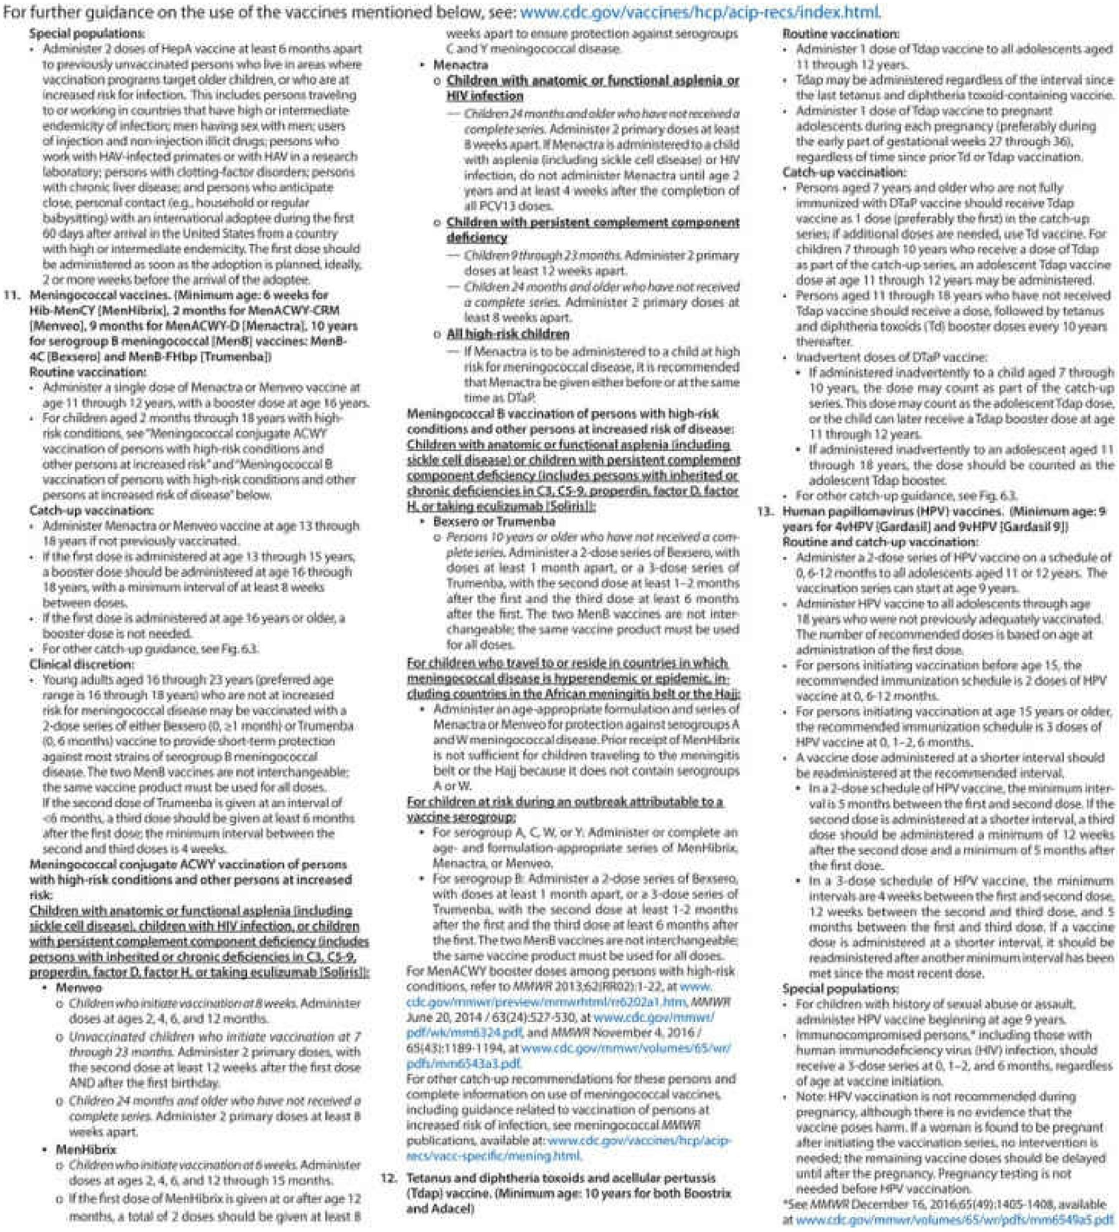
   Routine vaccination:
   - Administer a 2-dose series of VAR vaccine at ages 12 through 15 months and 4 through 6 years. The second dose may be administered before age 4 years, provided at least 3 months have elapsed since the first dose. If the second dose was administered at least 4 weeks after the first dose, it can be accepted as valid.

   Catch-up vaccination:
   - Ensure that all persons aged 7 through 18 years without evidence of immunity (see *MMWR* 2007;56[No. RR-4], available at www.cdc.gov/mmwr/pdf/rr/rr5604.pdf) have 2 doses of varicella vaccine. For children aged 7 through 12 years, the recommended minimum interval between doses is 3 months (if the second dose was administered at least 4 weeks after the first dose, it can be accepted as valid); for persons aged 13 years and older, the minimum interval between doses is 4 weeks.

10. **Hepatitis A (HepA) vaccine. (Minimum age: 12 months)**

    Routine vaccination:
    - Initiate the 2-dose HepA vaccine series at ages 12 through 23 months; separate the 2 doses by 6 to 18 months.
    - Children who have received 1 dose of HepA vaccine before age 24 months should receive a second dose 6 to 18 months after the first dose.
    - For any person aged 2 years and older who has not already received the HepA vaccine series, 2 doses of HepA vaccine separated by 6 to 18 months may be administered if immunity against hepatitis A virus infection is desired.

    Catch-up vaccination:
    - The minimum interval between the 2 doses is 6 months.



For further guidance on the use of the vaccines mentioned below, see: www.cdc.gov/vaccines/hcp/acip-recs/index.html.

Special populations:

- Administer 2 doses of HepA vaccine at least 6 months apart to previously unvaccinated persons who live in areas where vaccination programs target older children, or who are at increased risk for infection. This includes persons traveling to or working in countries that have high or intermediate endemicity of infection; men having sex with men; users of injection and non-injection illicit drugs; persons who work with HAV-infected primates or with HAV in a research laboratory; persons with clotting-factor disorders; persons with chronic liver disease; and persons who anticipate close, personal contact (e.g., household or regular babysitting) with an international adoptee during the first 60 days after arrival in the United States from a country with high or intermediate endemicity. The first dose should be administered as soon as the adoption is planned, ideally, 2 or more weeks before the arrival of the adoptee.

11. **Meningococcal vaccines. (Minimum age: 6 weeks for Hib-MenCY [MenHibrix], 2 months for MenACWY-CRM [Menveo], 9 months for MenACWY-D [Menactra], 10 years for serogroup B meningococcal [MenB] vaccines: MenB-4C [Bexsero] and MenB-FHbp [Trumenba])**

Routine vaccination:

- Administer a single dose of Menactra or Menveo vaccine at age 11 through 12 years, with a booster dose at age 16 years.
- For children aged 2 months through 18 years with high-risk conditions, see "Meningococcal conjugate ACWY vaccination of persons with high-risk conditions and other persons at increased risk" and "Meningococcal B vaccination of persons with high-risk conditions and other persons at increased risk of disease" below.

Catch-up vaccination:

- Administer Menactra or Menveo vaccine at age 13 through 18 years if not previously vaccinated.
- If the first dose is administered at age 13 through 15 years, a booster dose should be administeed at age 16 through 18 years, with a minimum interval of at least 8 weeks between doses.
- If the first dose is administered at age 16 years or older, a booster dose is not needed.
- For other catch-up guidance, see Fig. 6.3.

Clinical discretion:

- Young adults aged 16 through 23 years (preferred age range is 16 through 18 years) who are not at increased risk for meningococcal disease may be vaccinated with a 2-dose series of either Bexsero (0, ≥1 month) or Trumenba (0, 6 months) vaccine to provide short-term protection against most strains of serogroup B meningococcal disease. The two MenB vaccines are not interchangeable; the same vaccine product must be used for all doses.
  If the second dose of Trumenba is given at an interval of <6 months, a third dose should be given at least 6 months after the first dose; the minimum interval between the second and third doses is 4 weeks.

Meningococcal conjugate ACWY vaccination of persons with high-risk conditions and other persons at increased risk:

Children with anatomic or functional asplenia (including sickle cell disease), children with HIV infection, or children with persistent complement component deficiency (includes persons with inherited or chronic deficiencies in C3, C5-9, properdin, factor D, factor H, or taking eculizumab [Soliris]):

- **Menveo**
  - *Children who initiate vaccination at 8 weeks.* Administer doses at ages 2, 4, 6, and 12 months.
  - *Unvaccinated children who initiate vaccination at 7 through 23 months.* Administer 2 primary doses, with the second dose at least 12 weeks after the first dose AND after the first birthday.
  - *Children 24 months and older who have not received a complete series.* Administer 2 primary doses at least 8 weeks apart.
- **MenHibrix**
  - *Children who initiate vaccination at 6 weeks.* Administer doses at ages 2, 4, 6, and 12 through 15 months.
  - If the first dose of MenHibrix is given at or after age 12 months, a total of 2 doses should be given at least 8 weeks apart to ensure protection against serogroups C and Y meningococcal disease.
- **Menactra**
  - **Children with anatomic or functional asplenia or HIV infection**
    - — *Children 24 months and older who have not received a complete series.* Administer 2 primary doses at least 8 weeks apart. If Menactra is administered to a child with asplenia (including sickle cell disease) or HIV infection, do not administer Menactra until age 2 years and at least 4 weeks after the completion of all PCV13 doses.
  - **Children with persistent complement component deficiency**
    - — *Children 9 through 23 months.* Administer 2 primary doses at least 12 weeks apart.
    - — *Children 24 months and older who have not received a complete series.* Administer 2 primary doses at least 8 weeks apart.
  - **All high-risk children**
    - — If Menactra is to be administered to a child at high risk for meningococcal disease, it is recommended that Menactra be given either before or at the same time as DTaP.

Meningococcal B vaccination of persons with high-risk conditions and other persons at increased risk of disease:

Children with anatomic or functional asplenia (including sickle cell disease) or children with persistent complement component deficiency (includes persons with inherited or chronic deficiencies in C3, C5-9, properdin, factor D, factor H, or taking eculizumab [Soliris]):

- Bexsero or Trumenba
  - *Persons 10 years or older who have not received a complete series.* Administer a 2-dose series of Bexsero, with doses at least 1 month apart, or a 3-dose series of Trumenba, with the second dose at least 1–2 months after the first and the third dose at least 6 months after the first. The two MenB vaccines are not interchangeable; the same vaccine product must be used for all doses.

For children who travel to or reside in countries in which meningococcal disease is hyperendemic or epidemic, including countries in the African meningitis belt or the Hajj:

- Administer an age-appropriate formulation and series of Menactra or Menveo for protection against serogroups A and W meningococcal disease. Prior receipt of MenHibrix is not sufficient for children traveling to the meningitis belt or the Hajj because it does not contain serogroups A or W.

For children at risk during an outbreak attributable to a vaccine serogroup:

- For serogroup A, C, W, or Y: Administer or complete an age- and formulation-appropriate series of MenHibrix, Menactra, or Menveo.
- For serogroup B: Administer a 2-dose series of Bexsero, with doses at least 1 month apart, or a 3-dose series of Trumenba, with the second dose at least 1-2 months after the first and the third dose at least 6 months after the first. The two MenB vaccines are not interchangeable; the same vaccine product must be used for all doses.

For MenACWY booster doses among persons with high-risk conditions, refer to *MMWR* 2013;62(RR02):1-22, at www.cdc.gov/mmwr/preview/mmwrhtml/rr6202a1.htm, *MMWR* June 20, 2014 / 63(24):527-530, at www.cdc.gov/mmwr/pdf/wk/mm6324.pdf, and *MMWR* November 4, 2016 / 65(43):1189-1194, at www.cdc.gov/mmwr/volumes/65/wr/pdfs/mm6543a3.pdf.

For other catch-up recommendations for these persons and complete information on use of meningococcal vaccines, including guidance related to vaccination of persons at increased risk of infection, see meningococcal *MMWR* publications, available at: www.cdc.gov/vaccines/hcp/acip-recs/vacc-specific/mening.html.

12. **Tetanus and diphtheria toxoids and acellular pertussis (Tdap) vaccine. (Minimum age: 10 years for both Boostrix and Adacel)**

Routine vaccination:

- Administer 1 dose of Tdap vaccine to all adolescents aged 11 through 12 years.
- Tdap may be administered regardless of the interval since the last tetanus and diphtheria toxoid-containing vaccine.
- Administer 1 dose of Tdap vaccine to pregnant adolescents during each pregnancy (preferably during the early part of gestational weeks 27 through 36), regardless of time since prior Td or Tdap vaccination.

Catch-up vaccination:

- Persons aged 7 years and older who are not fully immunized with DTaP vaccine should receive Tdap vaccine as 1 dose (preferably the first) in the catch-up series; if additional doses are needed, use Td vaccine. For children 7 through 10 years who receive a dose of Tdap as part of the catch-up series, an adolescent Tdap vaccine dose at age 11 through 12 years may be administered.
- Persons aged 11 through 18 years who have not received Tdap vaccine should receive a dose, followed by tetanus and diphtheria toxoids (Td) booster doses every 10 years thereafter.
- Inadvertent doses of DTaP vaccine:
  - If administered inadvertently to a child aged 7 through 10 years, the dose may count as part of the catch-up series. This dose may count as the adolescent Tdap dose, or the child can later receive a Tdap booster dose at age 11 through 12 years.
  - If administered inadvertently to an adolescent aged 11 through 18 years, the dose should be counted as the adolescent Tdap booster.
- For other catch-up guidance, see Fig. 6.3.

13. **Human papillomavirus (HPV) vaccines. (Minimum age: 9 years for 4vHPV [Gardasil] and 9vHPV [Gardasil 9])**

Routine and catch-up vaccination:

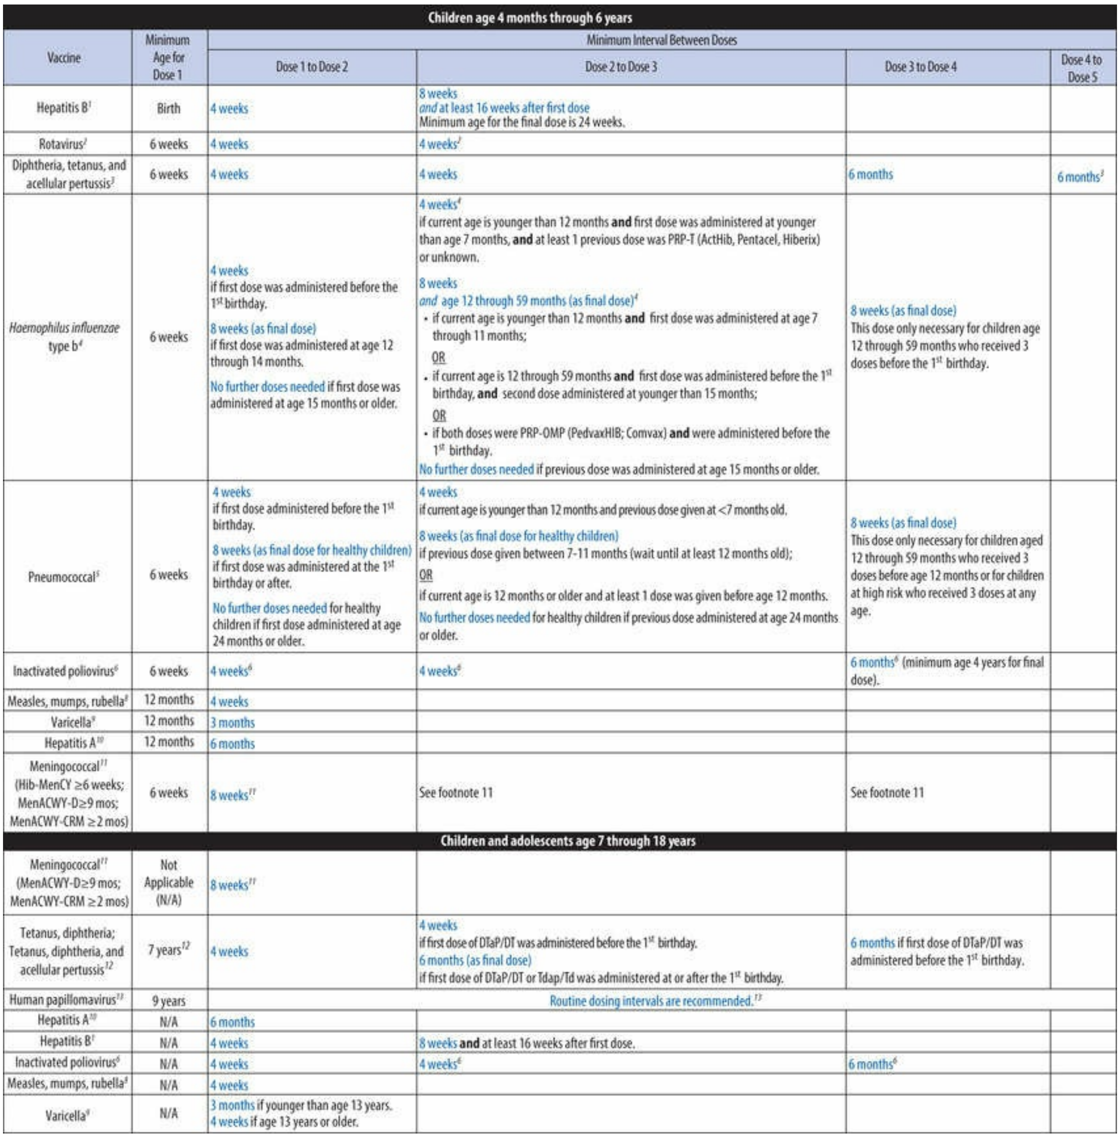
- Administer a 2-dose series of HPV vaccine on a schedule of 0, 6-12 months to all adolescents aged 11 or 12 years. The vaccination series can start at age 9 years.
- Administer HPV vaccine to all adolescents through age 18 years who were not previously adequately vaccinated. The number of recommended doses is based on age at administration of the first dose.
- For persons initiating vaccination before age 15, the recommended immunization schedule is 2 doses of HPV vaccine at 0, 6-12 months.
- For persons initiating vaccination at age 15 years or older, the recommended immunization schedule is 3 doses of HPV vaccine at 0, 1–2, 6 months.
- A vaccine dose administered at a shorter interval should be readministered at the recommended interval.
  - In a 2-dose schedule of HPV vaccine, the minimum interval is 5 months between the first and second dose. If the second dose is administered at a shorter interval, a third dose should be administered a minimum of 12 weeks after the second dose and a minimum of 5 months after the first dose.
  - In a 3-dose schedule of HPV vaccine, the minimum intervals are 4 weeks between the first and second dose, 12 weeks between the second and third dose, and 5 months between the first and third dose. If a vaccine dose is administered at a shorter interval, it should be readministered after another minimum interval has been met since the most recent dose.

Special populations:

- For children with history of sexual abuse or assault, administer HPV vaccine beginning at age 9 years.
- Immunocompromised persons,* including those with human immunodeficiency virus (HIV) infection, should receive a 3-dose series at 0, 1–2, and 6 months, regardless of age at vaccine initiation.
- Note: HPV vaccination is not recommended during pregnancy, although there is no evidence that the vaccine poses harm. If a woman is found to be pregnant after initiating the vaccination series, no intervention is needed; the remaining vaccine doses should be delayed until after the pregnancy. Pregnancy testing is not needed before HPV vaccination.

*See *MMWR* December 16, 2016;65(49):1405-1408, available at www.cdc.gov/mmwr/volumes/65/wr/pdfs/mm6549a5.pdf

FIGURE 6.2 **Recommended immunization schedule for persons 0 through 18 years of age: United States, 2017. For those who fall behind or start late, see the catch-up schedule (Fig. 6.3).** **(Modified from the National Center for Immunization and Respiratory Diseases, Centers for Disease Control and Prevention, Atlanta, Ga.)**



Children age 4 months through 6 years					
Vaccine	Minimum Age for Dose 1	Minimum Interval Between Doses			
		Dose 1 to Dose 2	Dose 2 to Dose 3	Dose 3 to Dose 4	Dose 4 to Dose 5
Hepatitis B[1]	Birth	4 weeks	8 weeks *and* at least 16 weeks after first dose Minimum age for the final dose is 24 weeks.		
Rotavirus[2]	6 weeks	4 weeks	4 weeks[2]		
Diphtheria, tetanus, and acellular pertussis[3]	6 weeks	4 weeks	4 weeks	6 months	6 months[3]
Haemophilus influenzae type b[4]	6 weeks	4 weeks if first dose was administered before the 1st birthday. 8 weeks (as final dose) if first dose was administered at age 12 through 14 months. No further doses needed if first dose was administered at age 15 months or older.	4 weeks[4] if current age is younger than 12 months **and** first dose was administered at younger than age 7 months, **and** at least 1 previous dose was PRP-T (ActHib, Pentacel, Hiberix) or unknown. 8 weeks *and* age 12 through 59 months (as final dose)[4] • if current age is younger than 12 months **and** first dose was administered at age 7 through 11 months; OR • if current age is 12 through 59 months **and** first dose was administered before the 1st birthday, **and** second dose administered at younger than 15 months; OR • if both doses were PRP-OMP (PedvaxHIB; Comvax) **and** were administered before the 1st birthday. No further doses needed if previous dose was administered at age 15 months or older.	8 weeks (as final dose) This dose only necessary for children age 12 through 59 months who received 3 doses before the 1st birthday.	
Pneumococcal[5]	6 weeks	4 weeks if first dose administered before the 1st birthday. 8 weeks (as final dose for healthy children) if first dose was administered at the 1st birthday or after. No further doses needed for healthy children if first dose administered at age 24 months or older.	4 weeks if current age is younger than 12 months and previous dose given at <7 months old. 8 weeks (as final dose for healthy children) if previous dose given between 7-11 months (wait until at least 12 months old); OR if current age is 12 months or older and at least 1 dose was given before age 12 months. No further doses needed for healthy children if previous dose administered at age 24 months or older.	8 weeks (as final dose) This dose only necessary for children aged 12 through 59 months who received 3 doses before age 12 months or for children at high risk who received 3 doses at any age.	
Inactivated poliovirus[6]	6 weeks	4 weeks[6]	4 weeks[6]	6 months[6] (minimum age 4 years for final dose).	
Measles, mumps, rubella[8]	12 months	4 weeks			
Varicella[9]	12 months	3 months			
Hepatitis A[10]	12 months	6 months			
Meningococcal[11] (Hib-MenCY ≥6 weeks; MenACWY-D≥9 mos; MenACWY-CRM ≥2 mos)	6 weeks	8 weeks[11]	See footnote 11	See footnote 11	
Children and adolescents age 7 through 18 years					
Meningococcal[11] (MenACWY-D≥9 mos; MenACWY-CRM ≥2 mos)	Not Applicable (N/A)	8 weeks[11]			
Tetanus, diphtheria; Tetanus, diphtheria, and acellular pertussis[12]	7 years[12]	4 weeks	4 weeks if first dose of DTaP/DT was administered before the 1st birthday. 6 months (as final dose) if first dose of DTaP/DT or Tdap/Td was administered at or after the 1st birthday.	6 months if first dose of DTaP/DT was administered before the 1st birthday.	
Human papillomavirus[13]	9 years	Routine dosing intervals are recommended.[13]			
Hepatitis A[10]	N/A	6 months			
Hepatitis B[1]	N/A	4 weeks	8 weeks **and** at least 16 weeks after first dose.		
Inactivated poliovirus[6]	N/A	4 weeks	4 weeks[6]	6 months[6]	
Measles, mumps, rubella[8]	N/A	4 weeks			
Varicella[9]	N/A	3 months if younger than age 13 years. 4 weeks if age 13 years or older.			

FIGURE 6.3 **Catch-up immunization schedule for persons 4 months through 18 years of age who start late or who are more than 1 month behind: United States, 2017. The figure provides catch-up schedules and minimum intervals between doses for children whose vaccinations have been delayed. A vaccine series does not need to be restarted, regardless of the time that has elapsed between doses. Use the section appropriate for the child's age. Always use this table in conjunction with the accompanying childhood and adolescent immunization schedule (see Fig. 6.2) and the respective footnotes (see Fig. 6.2 footnotes).** (Modified from the National Center for Immunization and Respiratory Diseases, Centers for Disease Control and Prevention, Atlanta, Ga.)

🟨 Vaccination according to the routine schedule recommended
🟪 Recommended for persons with an additional risk factor for which the vaccine would be indicated
▨ Vaccination is recommended, and additional doses may be necessary based on medical condition. See footnotes.
☐ No recommendation
🟥 Contraindicated
🟧 Precaution for vaccination

*Severe Combined Immunodeficiency

FIGURE 6.4 Vaccines that might be indicated for persons aged 0 through 18 years based on medical indications. These recommendations must be read along with the footnotes of this schedule found in Fig. 6.2.

Since its inception, the US immunization program has focused on immunization of infants and young children. In 1996, following growing concern about morbidity associated with vaccine-preventable diseases in the difficult-to-reach adolescent population, the ACIP recommended expanding efforts to immunize adolescents by establishing a routine vaccination visit at 11 to 12 years of age.[55] In addition to providing Td and previously missed vaccinations, the report emphasized that this visit should be used to provide other important preventive health services. The addition of several newer vaccines for adolescents (i.e., MCV4, Tdap, and HPV) stimulated a reappraisal of approaches that will most effectively and efficiently increase the proportion of adolescents who receive newly recommended vaccines and develop ways to integrate these approaches into other adolescent health, education, and development programs.[56]

Vaccine Spacing

Minimal spacing of vaccine doses generally is 1 month for the initial doses of killed vaccines; longer intervals are needed for booster doses to provide optimal responses.[8] For children with delayed initiation of immunization (after 6 months of age), an accelerated schedule is recommended (see Fig. 6.3).[8,57] To optimize adherence to the schedule in this circumstance, visits should be scheduled at 1-month intervals, and all recommended vaccines should be given at each visit. No need exists to restart any of the vaccine series in people with long delays between doses. The minimal spacing between nonsimultaneously administered live virus vaccines (e.g., MMR, varicella, and live, attenuated influenza) or repeated dose of the same live virus vaccine is 28 days.

Simultaneous Administration

All childhood vaccines can be administered simultaneously. This practice is based on extrapolation of data from multiple studies showing that most vaccines can be administered at the same time without compromising safety or immunogenicity.[58] Thus DTaP, Hib, IPV, HBV, PCV, MMR, varicella, and rotavirus vaccines can be administered simultaneously, and for inactivated vaccines within any interval of one another when otherwise indicated.[8,57] Lower geometric mean concentrations (GMCs) of IgG antibodies to some pneumococcal serotypes were observed compared with corresponding IgG GMCs when 7-valent PCV (PCV7) was administered alone. It is possible that the Menactra MCV4 (Sanofi Pasteur, Swiftwater, Pa) vaccine interferes with the immune response to 13-valent PCV (PCV13). Because of high risk for invasive pneumococcal disease, children with functional or anatomic asplenia or HIV infection should not be immunized with MenACWY-D (Menactra) before 2 years of age to avoid interference with the immune response to the PCV series.[59,59a] Data suggest possible immunologic interference in the meningococcal human complement serum bactericidal assay (hSBA) responses, resulting in decreased titers when MenACWY-D is administered 30 days after Daptacel (DTaP, Sanofi Pasteur). In contrast, coadministration of MenACWY-D and Daptacel was not associated with reduced hSBA responses to all four meningococcal serogroups. Available data do not allow evaluation of potential interference from other DTaP-containing vaccines on meningococcal seroresponse rates. If MenACWY-D is to be administered to a child at increased risk for meningococcal disease, the CDC recommends MenACWY-D be given either before or concomitantly with DTaP.[59a] Interference between live virus vaccines other than oral poliovirus vaccine (OPV) and rotavirus (e.g., MMR and varicella) theoretically can occur if they are given within a short interval; live virus vaccines should be given either simultaneously or at least 1 month apart. Vaccines should not be mixed in the same syringe unless specifically licensed for such use. Interference has been found between certain vaccines (cholera and yellow fever [YF]).

Spacing of Antibody-Containing Products and Vaccines

Immunoglobulins or blood products containing immunoglobulins inhibit response to certain live-virus vaccines (MMR and possibly varicella). The duration of inhibition of response is related to the dose of immunoglobulin delivered, and algorithms for calculating appropriate delays of MMR after receipt of such products are available.[22,57,60] In general, MMR vaccines should be delayed 3 months or longer after administration of usual doses of immunoglobulin (e.g., to prevent hepatitis A) or blood products and for longer periods after higher doses (e.g., 11 months after 2 g/kg immune globulin intravenous administered for treatment of Kawasaki disease).

Interchangeability of Vaccines

Available data support interchangeability of most vaccines produced by different manufacturers to prevent the same disease. Studies indicate that response to a 3-dose series using different Hib conjugate vaccines equals or exceeds that when the same vaccine is used for all doses.[61] The ACIP and AAP recommend that, when feasible, the same vaccine should be used for the primary series but that 3 doses of any vaccine are sufficient.[8,57] Data are limited regarding safety, immunogenicity, and efficacy of using acellular pertussis (as DTaP) vaccines from different manufacturers for successive doses of the pertussis series. Data suggest that 2 of the current DTaP preparations can be used interchangeably for the first 3 doses of the DTaP series without affecting safety or immunogenicity.[62] When the specific product is not known or available, any DTaP vaccine should be used to continue or complete the series. Similarly, any HPV vaccine can be used in populations for whom the vaccine is licensed to complete a series and protect against serotypes 16 and 18.[63]

Vaccine Safety and Compensation for Vaccine Injury

In 1986, the National Childhood Vaccine Injury Act was enacted to create a compensation program for families affected by childhood vaccine-associated adverse events and help ensure safety of the vaccine supply (Table 6.2).

TABLE 6.2

Outcomes From the National Childhood Vaccine Injury Act, 1986

National Vaccine Injury Compensation Program	• Limits manufacturer liability • Provides payments to families of children who sustain documented injuries following routine immunization
Vaccine Information Statement (VIS)	• A VIS must be given with every vaccination including each dose in a multidose series. Each VIS contains a brief description of the disease as well as the risks and benefits of the vaccine. The CDC develops VISs and distributes them to state and local health departments as well as individual providers
National Vaccine Program Office	• Develops and coordinates a comprehensive national vaccine plan
Advisory Commission on Childhood Vaccines	• Advises the Secretary of Health and Human Services on injury compensation program
National Vaccine Advisory Committee	• Advises the Secretary of Health and Human Services on national vaccine policy
Federal excise tax on childhood vaccines	• 1987 amendment to the Compensation Act • Proceeds used to finance payments to families of children affected by a vaccine-associated adverse event
Vaccine Adverse Events Reporting System	• Healthcare providers required to report certain adverse events (health effects occurring after immunization that may or may not be related to the vaccine)
Committee from the Institute of Medicine (IOM) to review literature on vaccine reactions	• IOM identified the following problems: 1. Limited understanding of biologic processes that underlie adverse events 2. Incomplete and inconsistent information from individual reports 3. Poorly constructed research studies (not enough people enrolled for the period of time) 4. Inadequate systems to track vaccine side effects 5. Few experimental studies published in the medical literature

Studies of Vaccine Safety

As many vaccine-preventable diseases approach or reach elimination in the US, continuing to balance the risks and benefits of each vaccine becomes increasingly important.[64] For example, OPV was formerly recommended for routine use in the US but was associated with vaccine-associated paralytic poliomyelitis (VAPP) in 1 case per 2.5 million vaccine doses distributed. This rare adverse event was no longer considered acceptable following elimination of poliomyelitis in the US, and in 2000, the ACIP recommended using IPV for all doses of poliovirus vaccine.[65] Public perceptions of vaccine safety are a challenge to the continued success of the vaccination program. New parents and younger physicians grew up without appreciating the morbidity and mortality of several vaccine-preventable diseases. Therefore risk or perception of risk for adverse events becomes an important concern.

In the early 1990s, the Institute of Medicine (IOM) reviewed available information regarding the possible causality of serious adverse events after administration of each of the then licensed childhood vaccines.[66–68] These reviews were updated in 2011.[67] For many events, information was considered insufficient to determine causality. For some events, however, the investigating panels classified events more definitively, as follows: (1) evidence establishes definitively that vaccine plays a causal role; (2) evidence supports a causal role for the vaccine; and (3) evidence indicates that the vaccine definitely does not play a causal role. These events are summarized in Table 6.3. These investigations represented a comprehensive compilation of data on vaccine safety, although controversy persists regarding certain events. Reanalysis of available data on the occurrence of type 1 diabetes mellitus after MMR or DTaP vaccination suggests that evidence favors rejection of a causal relationship.[69]

TABLE 6.3

Summary of Institute of Medicine and Agency for Healthcare Research and Quality Findings on the Relationship of Adverse

Events With Individual Vaccines

Vaccine	Established Causation/Convincingly Supports	Favors Causation/Acceptance	Favors Rejection of Causation
DT/Td/TT	Anaphylaxis	GBS[a] Brachial neuritis	Encephalopathy Type 1 diabetes Infantile spasms Death from SIDS
DTaP, Tdap (acellular pertussis)	—	—	Type 1 diabetes
DTP (whole cell pertussis)	Anaphylaxis; protracted, inconsolable crying	Acute encephalopathy Shock and unusual shock-like state (hypotonic-hyporesponsive episode) Chronic encephalopathy (after acute encephalopathy)	Infantile spasms Hypoarrhythmia Reye syndrome SIDS
Influenza	Anaphylaxis AHRQ: GBS (after 2009 monovalent H1N1 vaccine only)	Oculorespiratory syndrome Febrile seizures	(Inactivated) Bell palsy Asthma exacerbation or reactive airway episodes in children and adults (Inactivated) Cardiovascular and cerebrovascular events in older adults; serious adverse events in renal disease
IPV	—	—	—
Hepatitis B	Anaphylaxis	—	—
Hib (conjugate)	—	—	Early-onset *Haemophilus influenzae* b disease
HPV	Anaphylaxis	—	Type 1 diabetes, juvenile rheumatoid arthritis, GBS, appendicitis, seizures, stroke, syncope, venous thromboembolism
Measles	Death from measles vaccine strain in primarily immunocompromised persons Measles inclusion body encephalitis in persons with	Anaphylaxis	—

	immunodeficiencies		
Meningococcus	Anaphylaxis	—	—
MMR	Anaphylaxis Thrombocytopenia Febrile seizures	—	Autistic spectrum disorders Type 1 diabetes
Mumps (see MMR)	—	—	—
OPV	Poliomyelitis Death from polio vaccine strain, mainly in immunocompromised people	GBS[a]	—
Pneumococcal (conjugate)	—	Febrile seizures	—
Rotavirus	—	Intussusception	—
Rubella[b] (see MMR)	Anaphylaxis	Transient arthralgia in women Transient arthralgia in children	—
Varicella	Disseminated Oka VZV with (only in persons with immunodeficiencies) and without other organ involvement, e.g., pneumonia, meningitis, hepatitis) Vaccine strain viral reactivation without and with subsequent infection (meningitis, encephalitis) Anaphylaxis	—	—

[a] The Advisory Committee on Immunization Practice of the United States Public Health Service disagreed with these IOM findings (see reference 39).

[b] Data were reviewed by an earlier IOM committee. Initial report categories corresponding to those table headings were “Evidence indicates a causal relationship, Evidence is consistent with a causal relationship,” and “Evidence does not indicate a causal relationship.”

AHRQ, Agency for Healthcare Research and Quality; DT, diphtheria and tetanus toxoids; DTaP, diphtheria and tetanus toxoids and acellular pertussis; DTP, diphtheria and tetanus toxoids and pertussis (whole cell) vaccine; GBS, Guillain-Barré syndrome; Hib, *Haemophilus influenzae* type b conjugate vaccine; HPV, human papillomavirus; IOM, Institute of Medicine; IPV, inactivated poliovirus vaccine; MMR, measles, mumps, and rubella vaccine; OPV, live oral poliovirus vaccine; SIDS, sudden infant death syndrome; Td, tetanus and diphtheria toxoids; TT, tetanus toxoid; VZV, varicella-zoster virus.

Data from references 66 to 72.

As a result of continued concerns about vaccine safety, in 2000 the CDC and the National Institutes of Health commissioned the IOM to convene an Immunization Safety Review Committee.[70] Between 2001 and 2011, this independent expert committee published 9 reports related to various immunization safety concerns. The Committee has made recommendations in the areas of public health response, policy review, research, and communications for each of the 8 subjects reviewed (Box 6.1). The IOM concluded that the body of epidemiologic evidence favors rejection of a causal relationship between MMR vaccine and autism and concluded that no relationship exists between thimerosal-containing vaccines and autism.[70] None of the 9 IOM reports recommended a policy review of the current vaccine recommendations or change in the immunization schedule.[71] The most recent review by the IOM was charged to (1) review scientific findings and stakeholder concerns related to the safety of the recommended childhood immunization schedule and (2) identify potential research approaches, methodologies, and study designs that could inform this question, considering strengths, weaknesses, as well as the ethical and financial feasibility of each approach. The report concluded that the

Box 6.1

Institute of Medicine Immunization Safety Review Committee Reports and Dates of Release, 2001 to 2013

- Measles-Mumps-Rubella Vaccine and Autism (April 2001)
- Thimerosal-Containing Vaccines and Neurodevelopmental Disorders (October 2001)
- Multiple Immunizations and Immune Dysfunction (February 2002)
- Hepatitis B Vaccine and Demyelinating Neurological Disorders (May 2002)
- SV40 Contamination of Polio Vaccine and Cancer (October 2002)
- Vaccinations and Sudden Unexpected Death in Infancy (March 2003)
- Influenza Vaccines and Neurological Complications (October 2003)
- Vaccines and Autism (May 2004)

- Adverse Effects of Vaccines: Evidence and Causality (August 2011)
- Childhood Immunization Schedule and Safety: Stakeholder Concerns, Scientific Evidence, and Future Studies (January 2013)

> *… committee's efforts to identify priorities for recommended research studies did not reveal … evidence suggesting that the childhood immunization schedule is linked to autoimmune diseases, asthma, hypersensitivity, seizures or epilepsy, child developmental disorders, learning disorders or developmental disorders, or attention deficit or disruptive behavior disorders. While the committee found that there is no scientific evidence to justify the majority of safety concerns, perceptions dictate parental support and actions. Therefore further study of the full immunization schedule as well as further study to understand stakeholder perceptions and how they are formed can help improve awareness and education efforts.*[71]

In addition, the Agency for Healthcare Research and Quality commissioned an assessment of vaccine safety that evaluated evidence on the safety of vaccines recommended for routine use among adults, children, and pregnant women as of 2011.[72] This report included an extensive literature search for clinical trials and observational studies with strong study designs and analysis methods: cohort studies comparing vaccinated and unvaccinated groups, case-control studies, self-controlled case series, and designs using multivariate risk factor analyses. The results support most findings of the 2011 IOM report for vaccines routinely recommended for children, with some additional findings:

- “There is insufficient evidence to determine any potential association between trivalent inactivated vaccine and asthma exacerbation, acute disseminated encephalomyelitis, and transverse myelitis.
- Febrile seizures have been reported after DTaP, MMR, measles, mumps, rubella, and varicella (MMRV), inactivated influenza vaccine (IIV), and PCVs.[73,74] An analysis suggests that for DTaP, influenza, and PCV vaccines, only PCV vaccine is likely to cause febrile seizures when given alone or when given concomitantly with influenza or DTaP vaccines.[75]
- A large US postlicensure study found associations between both Rotarix and RotaTeq and intussusception in the short term following vaccination; patient-related risk factors were not reported.
- Strong evidence for a lack of association of HPV vaccines with several serious medical conditions (juvenile rheumatoid arthritis, type 1 diabetes, Guillain-Barré syndrome [GBS]) has been found in large postlicensure studies.
- Insufficient evidence has been found regarding other serious conditions such as multiple sclerosis, chronic inflammatory demyelinating polyneuropathy, amyotrophic lateral sclerosis, and pancreatitis.
- Insufficient evidence has been found to determine the possible association, if any, between vaccines such as DTaP, meningococcal vaccine, and varicella vaccine and the onset of nervous system conditions such as acute disseminated encephalomyelitis, transverse myelitis, multiple sclerosis, and GBS. Because these medical conditions are extremely rare, it may not be possible to reach a level of evidence beyond insufficient.”[72]

Monitoring of Vaccine Safety

A robust infrastructure consisting of several systems has been established to monitor vaccine safety following licensure. The Vaccine Adverse Event Reporting System (VAERS), operated jointly by the CDC and the FDA, is a national passive surveillance system used to detect early warning signals and generate hypotheses about possible new vaccine adverse events or changes in frequency of recognized events.[76] Intussusception associated with receipt of rhesus rotavirus vaccine and leading to its withdrawal from the market in 1999 was detected by the VAERS.[77,78] Physicians and vaccine manufacturers should report all suspected adverse reactions after vaccination to the VAERS and are required to report certain events.[31,76] Family members, patients, and others also can report adverse events to the VAERS. VAERS reports can be submitted electronically through a secure website at http://vaers.hhs.gov. A second CDC system is the Vaccine Safety Datalink (VSD), which consists of large, linked databases from integrated healthcare systems.[64,77,79] Associations between medically attended health events and immunizations can be evaluated through the VSD. A third system is the Clinical Immunization Safety Assessment (CISA) Centers network, which consists of selected clinical academic medical centers that work in partnership with the CDC to study the pathophysiology of vaccine reactions and develop clinical management protocols for affected patients. In addition, the FDA uses a sentinel surveillance program to study adverse events reported after vaccination, drug use, and use of medical devices. These systems are crucial to the vitality and strength of the US immunization program.

Compensation Program for Adverse Events After Immunization

In addition to mandating the review of causality of adverse events and creating a unified reporting system for adverse events after vaccination, the National Childhood Vaccine Injury Act established a program to provide compensation to people who experience permanent injury after vaccination.[31] A table of injuries eliciting automatic compensation was developed and has been revised on the basis of the findings of the IOM studies; in addition, any person who shows medical evidence of causality may be compensated. This program is funded by a special excise tax on each dose of vaccine ($0.75 per disease prevented) to which the program applies (i.e., diphtheria, tetanus, pertussis, Hib infection, poliomyelitis, measles, mumps, rubella, hepatitis A, hepatitis B, IPD, varicella, rotavirus infection, meningococcal disease, HPV infection, and influenza).

Vaccination in Special Situations

Infants Who Weigh Less Than 2000 Grams

Studies show that infants with birth weights of <2000 g may have a diminished response after administration of HBV vaccine at birth.[78] However, by 1 month chronologic age, all preterm infants, regardless of gestational age or weight at birth, are as likely to respond as older and larger infants.[22,57] Preterm infants born to hepatitis B surface antigen (HBsAg)–positive mothers and mothers with unknown HBsAg status should receive immunoprophylaxis with HBV vaccine and hepatitis B immunoglobulin (HBIG) within 12 hours of birth. If these infants weigh <2000 g at birth, the initial vaccine dose should not be counted toward completion of the HBV vaccine series, and 3 additional doses of vaccine should be administered, beginning when the infant is 1 month of age. Preterm infants weighing <2000 g and born to HBsAg-negative mothers should receive the first dose of the HBV vaccine series at 1 month of postnatal age (if medically stable) or at hospital discharge if the infant is younger than 1 month of age at discharge.

Pregnant Women

Risk of vaccination during pregnancy is largely theoretical. The benefit of vaccinating a pregnant woman outweighs the risk when the risk for disease exposure is high, infection may harm the mother or infant, and the vaccine is unlikely to cause harm. Tdap and influenza vaccines are indicated for all pregnant women. One randomized controlled trial conducted in Bangladesh that provided IIV to pregnant women during the third trimester demonstrated that infants born to vaccinated women had a 63% reduction in laboratory-confirmed influenza illness during the first 6 months of life, compared with pregnant women receiving 23-valent pneumococcal polysaccharide vaccine.[80] Maternal influenza vaccination during pregnancy was associated with significantly reduced risk for influenza virus infection (relative risk, 0.59; 95% confidence interval [CI], 0.37–0.93) and hospitalization for influenza-like illness (relative risk, 0.61; 95% CI, 0.45–0.84) among infants <6 months old in a nonrandomized prospective cohort study.[81] Women's healthcare providers should provide a maternal Tdap vaccination for every pregnant women during each pregnancy. Studies have demonstrated no statistically significant differences in rates of medically attended acute adverse events or adverse birth outcomes in pregnant women related to timing since previous tetanus-containing vaccination.[82,83] To maximize the maternal antibody response and passive antibody transfer to the infant, optimal timing for Tdap administration is early during the period of gestational weeks 27 through 36, regardless of time since prior Td or Tdap vaccination. For women not previously vaccinated with Tdap, if Tdap is not administered during pregnancy, Tdap should be administered immediately post partum.[84] Hepatitis B, hepatitis A, meningococcal, and pneumococcal vaccines can be given to pregnant women at high risk for these diseases.

The greatest concerns have been raised about live vaccines. MMR vaccine is contraindicated in pregnant women on theoretical grounds; however, because no case of congenital rubella syndrome has been reported after MMR vaccination among susceptible women exposed to rubella virus through MMR vaccine, inadvertent vaccination is not a reason to interrupt pregnancy. Varicella-containing vaccines also are contraindicated in pregnant women because of the theoretical risk that they can cause birth defects. Although the manufacturer's pregnancy registry closed in 2013, reporting of inadvertent immunization with a varicella-containing vaccine during pregnancy is encouraged.[85] Merck (Kenilworth, NJ) will continue to monitor pregnancy outcomes after inadvertent exposures to varicella-zoster virus–containing vaccines during pregnancy or within 3 months before conception. The CDC and FDA will continue to monitor adverse events after vaccination with varicella-zoster virus–containing vaccines through the VAERS. New cases of exposure immediately before or during pregnancy or other adverse events after vaccination with varicella-containing vaccines, should be reported to Merck (telephone: 877-888-4231) and to the VAERS (https://vaers.hhs.gov/index). Pregnancy in a household member is not a reason to postpone vaccination of other family members. In fact, vaccination of family members can be the best way to protect a pregnant mother from being exposed to natural infection. Breastfeeding does not adversely affect the responses to live or killed vaccines; breastfed infants should be vaccinated according to the recommended childhood and adolescent immunization schedule.[8]

Immunocompromised People

People with altered immunocompetence require special considerations for vaccination because they can be at increased risk for serious adverse consequences of disease or vaccination or poor response to vaccination.[22,28,57,86,87] The safety and efficacy of vaccines in people with immunodeficiencies are determined by the nature and degree of immunosuppression. Immunodeficiency conditions can be grouped into primary and secondary (acquired) disorders. Primary disorders of the immune system generally are inherited as single-gene disorders, can involve any part of the immune system, and share the common feature of susceptibility to infection with various organisms, depending on the specific deficiency. Categories of immunocompromised people with acquired immunodeficiency disorders include people with the following conditions: human immunodeficiency virus (HIV) infection; hematopoietic or solid-organ transplants; malignant diseases; immunosuppression resulting from administration of chemotherapy, systemic corticosteroids, radiation, monoclonal antibodies, or other drugs with significant side effects; and other chronic conditions, including splenectomy. People in these categories can be vaccinated safely with killed vaccines, which usually are recommended in the same doses and on the same schedules as for immunocompetent people. Response to both killed and live vaccines can be suboptimal, and higher doses or additional doses may be needed to ensure protection. Live vaccines generally are not recommended for any of these groups because of known or theoretical risks of disseminated infection resulting from the vaccine. Exceptions are MMR and varicella vaccines, which are either recommended or can be considered for susceptible people with HIV infection with $CD4^+$ T-lymphocyte counts ≥15% expected for age and no or mild symptoms of disease.[22,57,86,87] Table 6.4 shows recommendations for immunization of children and adolescents with primary and secondary immunodeficiencies.

TABLE 6.4

Vaccination of Children and Adolescents With Primary and Secondary Immunodeficiencies

Type of	Specific	Contraindicated	Risk-Specific	Effectiver

Type of Immunodeficiency	Specific Immunodeficiency	Contraindicated Vaccines[a]	Recommended Vaccines[a]	Effectiver Comment
PRIMARY				
B-lymphocyte (humoral)	Severe antibody deficiencies (e.g., X-linked agammaglobulinemia and common variable immunodeficiency)	OPV[b] Smallpox LAIV BCG Ty21a (live typhoid) Yellow fever Measles Mumps Rubella Varicella	Pneumococcal	The effect any vacci uncertain depends humoral (e.g., PPS MPSV4) IGIV inter the immu to measles and possi vaccine
	Less severe antibody deficiencies (e.g., selective IgA deficiency and IgG subclass deficiency)	OPV[b] BCG Yellow fever Other live vaccines appear to be safe	Pneumococcal Hib (if unimmunized)[c]	All vaccin effective; response attenuate
T-lymphocyte (cell-mediated and humoral)	Complete defects (e.g., SCID disease, complete DiGeorge syndrome)	All live vaccines[d,e,f]	Pneumococcal	Vaccines ineffective
	Partial defects (e.g., most patients with DiGeorge syndrome, Wiskott-Aldrich syndrome, ataxia-telangiectasia)	All live vaccines[d,e,f,g]	Pneumococcal Hib (if not administered in infancy)	Effectiven vaccine d degree of immunos
Complement	Persistent complement, properdin, or factor B deficiency	None	Pneumococcal Meningococcal conjugate ACWY, and B vaccines Hib (if unimmunized)[c]	All routin likely effe
Phagocytic function	Chronic granulomatous disease, leukocyte adhesion defect, and myeloperoxidase deficiency	Live bacterial vaccines[d]	Pneumococcal[h]	All inacti vaccines s likely effe Live viral likely safe effective
SECONDARY	HIVc/AIDS	OPV[b] Smallpox BCG LAIV Meningococcal conjugate ACWY Withhold MMR and varicella in severely immunocompromised persons Yellow fever vaccine may have a contraindication or a precaution depending on clinical parameters	Pneumococcal Hib (if unimmunized[c])	MMR, va rotavirus, inactivate including effective[i]

		of immune function

	Asplenia	LAIV	Pneumococcal Meningococcal conjugate ACWY, and B vaccines Hib (if unimmunized[c])	All routin likely effe
	Chronic renal disease	LAIV	Pneumococcal Hepatitis B[j]	All routin likely effe
	After allogeneic or autologous hematopoietic stem cell transplantation	LAIV Rotavirus	IIV Pneumococcal Hib	All other recomme inactivate should be administe Rubin LG Ljungmar 2013 IDS practice g vaccinatic immunoc host. Clin 2014;58:e4 detailed s

[a] Other vaccines that are universally or routinely recommended should be given if not contraindicated.

[b] OPV is no longer available in the United States.

[c] Children who have not received a primary series and booster dose or at least 1 dose of Hib vaccine after 14 months of age are considered unimmunized.

[d] Live bacterial vaccines: BCG and oral Ty21a *Salmonella typhi* vaccine.

[e] Live viral vaccines: MMR, MMRV, OPV, LAIV, yellow fever, zoster, rotavirus, varicella, and vaccinia (smallpox). Smallpox vaccine is not recommended for children or the general public.

[f] Regarding T-lymphocyte immunodeficiency as a contraindication for rotavirus vaccine, data exist only for SCID.

[g] Children with partial DiGeorge syndrome should undergo immune system assessment of lymphocyte subsets and mitogen responsiveness to determine whether they should be given live viral vaccines. Those with ≥500 CD3 T lymphocytes/mm^3, ≥200 CD8 T lymphocytes/mm^3, and normal mitogen response should receive MMR and varicella vaccines.

[h] Pneumococcal vaccine is not indicated for children with chronic granulomatous disease beyond age-based universal recommendations for PCV. Children with chronic granulomatous disease are not at increased risk for pneumococcal disease.

[i] HIV-infected children should receive IG after exposure to measles and can receive varicella and measles vaccine if CD4$^+$ T-lymphocyte count is ≥15%.

[j] Indicated based on the risk from dialysis-based bloodborne transmission.

[j] Indicated based on the risk from dialysis-based bloodborne transmission.

[k] Symptomatic HIV infection or CD4$^+$ T-lymphocyte count of <200/mm^3 or <15% of total lymphocytes for children <6 years of age is a contraindication to yellow fever vaccine administration. Asymptomatic HIV infection with CD4$^+$ T-lymphocyte count of 200 to 499/mm^3 for persons ≥6 years of age or 15% to 24% of total lymphocytes for children <6 years old is a precaution for yellow fever vaccine administration. Details of yellow fever vaccine recommendations are available from the Centers for Disease Control and Prevention.[226]

AIDS, acquired immunodeficiency syndrome; BCG, bacille Calmette-Guérin; Hib, *Haemophilus influenzae* type b; HIV, human immunodeficiency virus; IG, immunoglobulin; IgA, immunoglobulin A; IgG, immunoglobulin G; IGIV, immune globulin intravenous; IIV, inactivated influenza vaccine; LAIV, live, attenuated influenza vaccine; MMR, measles, mumps, and rubella; MPSV4, quadrivalent meningococcal polysaccharide vaccine; OPV, oral poliovirus vaccine (live); PCV, pneumococcal conjugate vaccine; PPSV, pneumococcal polysaccharide vaccine; SCID, severe combined immunodeficiency.

Data from Centers for Disease Control and Prevention. General recommendations on immunization: recommendations of the Advisory Committee on Immunization Practices (ACIP). MMWR Morb Mortal Wkly Rep 2011;60:2; and Rubin LG, Levin MJ, Ljungman P, et al. 2013 IDSA clinical practice guideline for vaccination of the immunocompromised host. Clin Infect Dis 2014;58:e44–e100.

International Travelers

International travelers frequently have increased risk of exposure to vaccine-preventable diseases, even in economically developed countries. Parents and physicians of children and adolescents planning international travel should ensure that all routine childhood and adolescent immunizations are up to date and that adults are up to date on their immunizations. Infants ≥6 months of age should be given MMR vaccine. The need for other vaccines should be determined through consultation with specific guidelines for travelers.[88] Additional information for international travelers can be found on the CDC website at www.cdc.gov/travel or the World Health Organization (WHO) website at www.who.int/ith/en.

Immigrants

The immunization status of all children emigrating from other countries should be reviewed on entry of these children into the US, and necessary vaccinations should be administered. Since 1996, the Immigration and Naturalization Act has required that people seeking permanent US residency show proof of having received the immunizations that are documented on an immunization record generally can be presumed to have been effective. Doses that are consistent in initial timing and intervals with US recommendations can be considered acceptable, and only doses required to comply with US recommendations for age need be given.[8] If a child has no immunization record, the immunization series should be initiated; the most significant risk of serious reaction may be to the tetanus component of DTP or DTaP, for which immunization in the presence of high levels of antibody resulting from previous undocumented immunization can cause serious local Arthus-type reactions.[57]

International Adoptees

Studies have shown that immunization records for international adoptees from some areas (e.g., Eastern Europe, the former Soviet Union, and China), especially children from orphanages, may not accurately reflect protection because of inaccurate or unreliable records, lack of vaccine potency, poor nutritional status, or other problems. For any international adoptee, if a question exists about whether vaccines were administered or were immunogenic, the best course is to administer all vaccines recommended by age. If avoiding unnecessary injections is desired, the judicious use of serologic testing can help to determine which injections can be avoided (see Chapter 4).

Other Programmatic Issues

Responsibility for ensuring that children and adolescents are immunized adequately lies with parents and primary care providers. For children and adolescents without primary healthcare providers, public and hospital-based clinics provide immunizations through federal- and state-funded programs. Each child's immunization status should be assessed every time the child is seen for healthcare, whether for preventive care or curative treatment. Physicians should ensure that each child has an immunization record and that the record is updated each time an immunization is given.[89] Parents should be encouraged to bring the immunization record for each healthcare visit. Immunization information systems (i.e., immunization registries) are intended to compile and make record for each healthcare visit. Immunization information systems (i.e., immunization registries) are intended to compile and make available to all providers the immunization records of all children in a city or state. These registries will provide a system whereby reminders about impending or missed immunizations can be generated and providers can gain access to a reliable record for mobile children.[90]

Clinical Practice Guidelines for Child and Adolescent Immunization

The Infectious Diseases Society of America (IDSA) developed specific guidelines for child and adolescent immunization practices to help providers maintain practices that optimize the immunization status of children and adults.[89] These are guidelines for appropriate clinical practices, including identification of appropriate contraindications to immunization (www.cdc.gov/vaccines/hcp/admin/contraindications-vacc.html), use of tracking systems, and avoidance of missed opportunities. The Task Force for Community Preventive Services extensively reviewed the scientific literature regarding best practices to improve immunization of young children.[91–94] The most effective and most strongly recommended interventions are divided into the following categories: (1) interventions that increase community demand for vaccines (client reminder-recall systems, education, and vaccination requirements for school, childcare, and college attendance); (2) interventions that enhance access to vaccination services (reducing out-of-pocket costs for vaccination and expanding access in medical or public health settings); and (3) interventions that use provider-based interventions (reminder-recall and assessment and feedback for vaccine providers). Conducting audits of patients' immunization records in both public clinics and private providers' offices is recommended to educate providers about the immunization status of patients, as well as to identify practices that can be changed to improve immunization coverage. Routine use of audits in public clinics has reduced missed opportunities for immunization and markedly improved immunization coverage. Self-assessment methods are available from the CDC and AAP.

immunization programs. The National Childhood Vaccine Injury Act mandated that parents should be provided with written materials for vaccines covered by the Vaccine Injury Compensation Program that describe the diseases that vaccines are intended to prevent, the risks and benefits of the vaccines, and the procedure for reporting adverse events and seeking compensation for vaccine-related injury.[31] Vaccine information statements are available at http://www.cdc.gov/vaccines/hcp/vis/index.html.

Vaccine Shortages

In addition to the rising cost of vaccines, unparalleled numbers of vaccine shortages in the US have had a substantial impact on vaccine delivery. From 2000 through 2010, vaccine shortages, vaccine supply issues, and changes in routine recommendations occurred for almost all vaccines in the childhood and adolescent immunization schedule.[95–102] The shortages affected millions of children and their healthcare providers and even triggered suspension of school entry requirements for vaccines.[102–104]

The causes of these widespread vaccine shortages are multifactorial, but an important factor is the decrease in the number of manufacturers of childhood vaccines. In 1993, 6 manufacturers produced the 6 vaccines. Currently, although several vaccines (PCV13, varicella, influenza, Tdap, rotavirus, MMRV, hepatitis A, herpes zoster, MCV, and HPV) have been added to the recommended schedules, the number of manufacturers has increased to only 8. In addition, many of the childhood and adolescent vaccines (MMR, MMRV, varicella, and PCV13) have a single manufacturer. In response to concerns over the fragility of the US vaccine supply, the General Accounting Office and National Vaccine Advisory Committee both conducted in-depth reviews of the vaccine shortages, concluded that future disruptions in vaccine supply are likely to continue, and proposed several solutions.[95,105] The current status of vaccine shortages in the US can be found at www.cdc.gov/vaccines/hcp/clinical-resources/shortages.html.

Handling and Storage of Vaccines

Vaccines are perishable products that require specific care in

Vaccines are perishable products that require specific care in handling and storage; ensuring that a vaccine maintains potency and safety is a responsibility shared by the manufacturer and all people handling the vaccine. Live, attenuated vaccines are more susceptible to degradation when exposed to temperature extremes, and inactivated vaccines (particularly those containing adjuvants) and toxoids must be protected from freezing to ensure potency.[22] Vaccines that are exposed to damaging environmental conditions can suffer loss of potency without a change in appearance. A vaccine quality control program should be established in each clinical practice and should focus on education of personnel, maintenance of equipment, and adherence to established daily monitoring of vaccines.[31] Recommendations and materials about vaccine storage and handling can be accessed at www.cdc.gov/vaccines/hcp/admin/storage/index.html.

Vaccine Financing

Ensuring that all children and adolescents, regardless of health insurance status or income level, have access to recommended vaccines requires a complex system of financing that includes private and public funding mechanisms (Table 6.5). In 2013, 53% of US children received vaccines purchased through the public sector, and 47% received vaccines purchased through the private sector. Most of the public-purchase vaccines are financed through the Vaccines for Children (VFC) program, an entitlement program established in 1994 as part of the Social Security Act.[31] Other government funding mechanisms include federally purchased vaccines through the discretionary Immunization Program, authorized under Section 317 of the Public Health Service Act of 1962, and state and local government funding. These programs support states to provide immunizations to children and adults who do not qualify for the VFC program but who are not covered by private insurance. Several states use a combination of federal and state funding to purchase and distribute vaccines recommended for children to all immunization providers in private and public sectors. Insurance programs provide vaccines for children in the private sector. The Affordable Care Act requires insurers to cover ACIP-recommended vaccines at in-network (http://www.hhs.gov/healthcare/facts-and-features/fact-sheets/aca-and-immunization/index.html). Thus, all children with insurance should not have financial barriers to access if they seek vaccinations at in-network providers.

TABLE 6.5

Major Financing Programs for Childhood Immunization

Variable	Vaccines for Children Program	Section 317 Immunization Grant Program	State/Local Government	Private Insurance
Financing source	Entitlement funded through Medicaid trust fund	Annual discretionary appropriation by Congress	Appropriations through state or local legislatures	Employer-based insurance
Eligibility	Age <19 years and membership in ≥1 of the following categories: Medicaid-eligible; uninsured; Alaska Native or American Indian; or underinsured at a federally qualified health center or rural health clinic	No federal eligibility restrictions	Varies by state or local area	Persons covered by private insurance, including Employee Retirement Income Security Act (ERISA) plans
Financing of new vaccines and recommendations	Vote of ACIP and establishment of a federal contract; funds are approved by the Office of Management and Budget	Funding appropriated by Congress annually	Funding must be sought from state legislatures	As of September 2010, new health plans must cover ACIP-recommended vaccines with no copay or deductible when provided by an in-network provider
Proportion of childhood vaccine market purchased	46%	4%	3%	47%

ACIP, Advisory Committee on Immunization Practices.

Surveillance for Vaccine-Preventable Diseases

Surveillance for vaccine-preventable diseases is mandated by each

Surveillance for vaccine-preventable diseases is mandated by each state, and data are compiled in the CDC National Notifiable Disease Surveillance System and available at www.cdc.gov/mmwr.[106] These data are monitored to assess the effectiveness of vaccines and vaccination programs. For each reported case of disease, confirmation of disease by laboratory testing and documentation of the patient's vaccination status are critical to determining whether continued occurrence of disease is the result of failure to deliver vaccine or failure of vaccine. As programs approach elimination of indigenous transmission, determining chains of disease transmission, as well as whether the case is indigenous or imported, and rapid implementation of control measures also become critical. All physicians are urged to report all suspected cases of vaccine-preventable diseases promptly to their local and state health departments.

Routine Childhood and Adolescent Vaccines

Diphtheria and Tetanus Toxoids and Pertussis Vaccines

In 1980, cutaneous diphtheria was no longer a nationally notifiable disease in the US. Between 1980 and 2014, 57 cases of respiratory tract diphtheria were reported.[107,108] From 2001 through 2014, 397 cases of tetanus were reported in the US, with a peak of 41 cases in 2006.[36,108] Since 2003, the number of reported cases of pertussis has increased each year through 2012, with a peak of 48,277 cases in 2012.[109] More than 28,000 cases were reported in each of 2013 and 2014, and 18,166 were reported in 2015.[109] Changes in pertussis vaccine recommendations for the newer Tdap vaccine were published between 2010 and 2012.[84,110,111] Although infants have the highest incidence of pertussis and morbidity associated with pertussis, adolescents and adults account for the majority of reported cases.[112]

Immunization of children and adolescents to prevent diphtheria, tetanus, and pertussis usually is completed with a vaccine composed of diphtheria and tetanus toxoids combined with an acellular pertussis component.[110,113–115] Diphtheria and tetanus toxoids are purified preparations of formalin-inactivated diphtheria and tetanus toxins, respectively. Table 6.6 shows the composition and recommended use of vaccines with tetanus toxoid, diphtheria toxoid, and acellular pertussis components licensed in the US for children <7 years of age and people ≥7 years of age. Whole cell DTP was the only pertussis vaccine available from 1948 through 1992; because of its relatively high rate of adverse reactions compared with the newer acellular pertussis vaccines, DTP is no longer used in the US.[113] Whole cell DTP continues to be the most frequently used pertussis-containing vaccine worldwide.

TABLE 6.6

Composition of Selected Vaccines With Tetanus Toxoid, Diphtheria Toxoid, and Acellular Pertussis Components Licensed

in the United States, 2015

Vaccines for Children <7 Yr of Age	**Trade Name**	**PT (µg/dose)**	**FHA (µg/dose)**	**PRN (µg/dose)**	**FIM (µg/dose)**	**Recommended Use**
DTaP	Infanrix	25	25	8	—	All 5 doses
DTaP-IPV-HepB	Pediarix	25	25	8	—	First 3 doses
DTaP	Daptacel	10	5	3	5	All 5 doses
DTaP-IPV/Hib	Pentacel	20	20	3	5	First 4 doses
DTaP-IPV	Kinrix	25	25	8	—	Fifth dose only
DTaP-IPV	Quadracel	20	20	3	5	Fifth dose only
DT	No trade name	—	—	—	—	Use instead of DTaP if pertussis contraindicated
Vaccines for People ≥7 Yr of Age						
Tdap	Boostrix	8	8	2.5	—	Single dose indicated for people 10 yr of age and older
Tdap	Adacel	2.5	5	3	5	Single dose indicated for people 11–64 yr of age
Td	Several	—	—	—	—	Every 10 yr

DT, diphtheria and tetanus toxoids; DTaP, diphtheria and tetanus toxoids and acellular pertussis for use <7 years of age; FHA, filamentous hemagglutinin antigen; FIM, fimbriae; HepB, hepatitis B; IPV, inactivated poliovirus vaccine; PRN, pertactin; PT, pertussis toxoid, Td, tetanus and diphtheria toxoids for use ≥7 years of age; Tdap, tetanus toxoid, and reduced diphtheria toxoid, and acellular pertussis vaccine for use in adolescents.

Recommendations for DTaP Immunization for Children Younger Than 7 Years of Age

Immunization with DTaP vaccine is recommended for all children <7 years of age. Primary vaccination consists of 3 doses of DTaP vaccine given at 2, 4, and 6 months of age; the minimal age for initiating vaccination is 6 weeks, and the minimal interval between doses is 4 weeks (see Fig. 6.2).[113–115] To ensure protection, a reinforcing dose of DTaP is given at 15 to 18 months of age and at school entry (4 through 6 years of age). Diphtheria and tetanus (DT) toxoids are used in children for whom pertussis vaccination is contraindicated. If the schedule is interrupted, the series does not need to be restarted.

The vaccination advisory bodies consider data insufficient to support expression of a preference among the different acellular pertussis vaccines.[113] Whenever feasible, the same brand of DTaP vaccine should be used for all doses of the primary vaccination series (3 doses on a standard schedule), although data suggest that the 2 available preparations can be used interchangeably for the first 3 doses of the series.[62] If the provider does not know or does not have available the type of DTaP vaccine previously administered, any of the DTaP vaccines can be used to complete the series. DTaP vaccines can be given simultaneously with other recommended childhood vaccines (HBV, Hib, IPV or OPV, PCV13, rotavirus) at 2, 4, and 6 months of age, and they can be given with these vaccines as well as with MMR, varicella, and HAV vaccines at 15 through 18 months of age. DTaP is not licensed for use in adults or in children ≥7 years of age. Vaccination to prevent diphtheria and tetanus is recommended for previously unvaccinated children (≥7 years of age and in whom pertussis vaccine is contraindicated) and adults. Children 7 through 10 years of age who are not fully immunized with DTaP against pertussis should receive a single dose of Tdap.[8,110]

Immunity often wanes in the few years following vaccination with acellular pertussis vaccines.[116,117] Thus clinicians should suspect pertussis in persons with clinically compatible symptoms. At present, no recommendations for additional boosters with Tdap exist for the general population with the exception of pregnant women, for whom Tdap is recommended during each pregnancy.

Use of tetanus toxoid–containing preparations, with or without tetanus immunoglobulin, can be indicated after penetrating or other types of injuries in people who are not adequately vaccinated.[115] For any such person who has not previously received the 3-dose primary series, initiation or continuation of the primary vaccination appropriate for age (DTaP, Tdap, DT, or Td) is recommended after any wound. Vaccination is not necessary in people who have received 3 previous doses of tetanus vaccine, except in the following circumstances: (1) the last vaccination occurred more than 10 years previously (5 years for wounds, other than clean and minor wounds); or (2) only 3 doses of fluid (nonadjuvant) tetanus toxoid were received, in which case 1 dose of Td vaccine should be given (see Chapter 188).[115]

Precautions and Contraindications.

Vaccination with any pertussis-containing vaccine is contraindicated in any child who has had an anaphylactic reaction to any component of the vaccine or has experienced acute encephalopathy not attributable to another identifiable cause within 7 days of administration of a previous dose.[113] The following events are considered precautions to pertussis immunization: (1) temperature ≥40.5°C within 48 hours of a previous dose not attributed to another cause; (2) collapse or shock-like state (hypotonic-hyporesponsive episode) within 48 hours of DTP or DTaP administration; (3) persistent, inconsolable crying (≥3 hours) within 48 hours of administration of DTP or DTaP; and (4) convulsions with or without fever within 3 days of immunization. When these events occur, the physician can elect to continue vaccination if the benefits are judged to outweigh the risks, such as when a pertussis outbreak is occurring in the community. DTaP immunization should be deferred in children with evolving neurologic disorders until the situation is clarified; when the condition is stable, the child should be given DTaP vaccine. Decisions about pertussis vaccination of such children should be made before the first birthday. If pertussis vaccine is not used, pediatric DT should be administered.

Recommendations for Tdap Immunization for Adolescents 11 Through 18 Years of Age

Adolescents 11 through 18 years of age should receive a single dose of Tdap instead of Td for booster immunization against tetanus, diphtheria, and pertussis if they have completed the recommended childhood DTP/DTaP vaccination series and have not received Tdap.[8] The preferred age for Tdap vaccination is 11 to 12 years of age (see Fig. 6.2).

Adolescents 11 through 18 years of age who received Td, but not Tdap, are encouraged to receive a single dose of Tdap to provide protection against pertussis if they have completed the recommended childhood DTP/DTaP vaccination series.[84,110] If more doses of tetanus and diphtheria toxoids are needed to complete the primary series (after 1 dose of Tdap) in such older children, Td should be used.

Contraindications, Precautions, and Reasons to Defer Tdap

or Td Among Adolescents 11 Through 18 Years of Age.

Contraindications to Tdap include a history of serious allergic reaction (i.e., anaphylaxis) to vaccine components or encephalopathy (e.g., coma or prolonged seizures) not attributable to an identifiable cause within 7 days of administration of a vaccine with pertussis components. This is a contraindication to use of the pertussis components; Td can be used.

Precautions and reasons to defer Tdap include the following: GBS occurring <6 weeks after a previous dose of a tetanus toxoid–containing vaccine; progressive neurologic disorder, including progressive encephalopathy, or uncontrolled epilepsy, until the condition has stabilized (these conditions are precautions for the pertussis components; Td can be used); moderate or severe acute illness; and history of an Arthus reaction after a tetanus toxoid–containing or diphtheria toxoid–containing vaccine administered <10 years previously.

Special Situations for Tdap (Single-Dose) and Td Use Among Adolescents 11 Through 18 Years of Age.

If simultaneous vaccination is not feasible, inactivated vaccines can be administered at any time before or after a different inactivated or live vaccine. The ACIP recommends that Tdap (or Td) and MCV4 vaccines (which all contain diphtheria toxoid) can be administered using any sequence and timing.[8,39,110] The following situations for administration of Tdap should be considered:

- Use of Td when Tdap is not available. When Tdap is indicated but not available, vaccine providers should administer Td if the last pediatric DTP, DTaP, DT, or Td dose was >10 years earlier, to provide protection against tetanus and diphtheria.
- Tetanus prophylaxis in wound management. Adolescents who require a tetanus toxoid–containing vaccine as part of wound management should receive a single dose of Tdap instead of Td if they previously have not received Tdap; if Tdap is not available or previously was administered, adolescents who need a tetanus toxoid–containing vaccine should receive Td, and if Td is not available, adolescents who previously received Tdap should receive Tdap.
- History of pertussis. Adolescents who have a history of pertussis

generally should receive Tdap according to the routine recommendations.

- No history of pertussis vaccination. Adolescents who have not received vaccines with pertussis components but who have completed the recommended tetanus and diphtheria vaccination series with pediatric DT or Td should generally receive Tdap according to the routine recommendations if they do not have a contraindication to the pertussis components.
- No history of pediatric DTP/DTaP or Td/Tdap vaccination. Adolescents who have never received tetanus-diphtheria-pertussis vaccination should receive a series of 3 vaccinations. The preferred schedule is a single Tdap dose, followed by a dose of Td ≥4 weeks after the Tdap dose and a second dose of Td 6 to 12 months after the earlier Td dose. Tdap can be substituted for any 1 of the 3 Td doses in the series.
- Use of Td and Tdap in pregnant adolescents. See the earlier section on pregnant women. Manufacturers of Boostrix (GlaxoSmithKline Biologicals, Philadelphia; telephone: 888-825-5249), and Adacel (Sanofi Pasteur; telephone: 800-822-2463) maintain pregnancy registries for Tdap as required by the FDA at licensure. Providers can report Tdap administrations to the appropriate manufacturer.[39,84]

Haemophilus influenzae Type b Conjugate Vaccines

Before introduction of conjugated Hib vaccines in 1987, the incidence of invasive Hib diseases among children <5 years of age was estimated to be 1 cases in 1000. In 2014, 472 cases of invasive disease caused by *H. influenzae* were reported in children <5 years of age; of these cases, 9% were type b, and 92% were of unknown serotype.[36,108] In 2015, 23 cases of *H. influenzae* type b disease were reported.[117a]

Hib conjugate vaccines, first licensed for 18-month-old children in 1987 and for infants 2 months of age and older in 1990, have replaced the polysaccharide vaccines available from 1985 to 1989.[118] Hib conjugate vaccines contain Hib polysaccharide covalently linked with a protein carrier, which induces a T-lymphocyte–

dependent immune response and immune memory not induced by polysaccharide (polyribosylribitol phosphate [PRP]) vaccine alone. The carrier protein for the vaccines licensed for infants is either tetanus toxoid (PRP-T) or the outer membrane protein (OMP) of *Neisseria meningitidis* (PRP-OMP). Two combination vaccines containing either PRP-OMP or PRP-T are available.

When given as a 2-dose (PRP-OMP) or 3-dose (PRP-T) primary series to infants, Hib vaccine induces a high level of antibody to Hib polysaccharide that wanes over the next 6 through 15 months; a booster dose is therefore needed at 12 through 15 months of age. PRP-OMP induces a substantial response after a single dose and may be preferred for populations at highest risk of infant infection (Native Americans, including Alaska Natives); PRP-T vaccines require 3 doses for optimal response in infants.[118] Controlled trials showed 93% to 100% efficacy for PRP-OMP in infants in the US; licensing of PRP-T was based on comparable immunogenicity and 95% efficacy data from a British trial.[118] Several studies have shown that giving different Hib vaccines during the primary series induces a response similar to that induced by a primary series with the same vaccine and that booster doses with different vaccines induce strong responses.[61,118]

Recommendations for Immunization

Hib vaccination is recommended for all infants, starting at 6 weeks to 2 months of age (see Fig. 6.2).[8,57,86,118] For PRP-T, the primary series consists of 3 doses and should be administered at 2, 4, and 6 months of age. The primary series with PRP-OMP consists of 2 doses and should be administered at 2 and 4 months of age; a dose at age 6 months is not indicated. One booster dose (dose 3 or 4, depending on the vaccine used in the primary series) of any Hib vaccine should be administered at age 12 through 15 months. When primary immunization is delayed, the number of doses is reduced; for children vaccinated beginning at 7 through 11 months of age, 2 primary doses are recommended with a 1-month interval, followed by a booster at 12 through 15 months of age, at least 2 months after the second dose. If vaccination is initiated at 12 through 14 months of age, 2 doses with an 8-week interval are indicated. For initiation of vaccination in children 15 through 59 months of age, a single dose of any of the licensed vaccines is recommended. Although the primary series ideally should be completed with the same vaccine, 3 doses of any vaccine are recommended if the initial vaccine is not available or is unknown. Booster doses can consist of any of the licensed vaccines. Hib vaccines can be given simultaneously with all other childhood vaccines, including DTaP, IPV or OPV, hepatitis B, PCV13, MMR, varicella, hepatitis A, and rotavirus vaccines.[118]

Children considered at high-risk for Hib disease include the following: children with sickle cell disease, splenectomy, HIV infection, immunoglobulin deficiency (including immunoglobulin G_2 subclass deficiency), or early component complement deficiency; recipients of a hematopoietic stem cell transplant; and those receiving chemotherapy or radiation therapy for malignant neoplasms; these children may need additional doses of Hib vaccine, but the vaccine may not be as highly immunogenic as in healthy children.[23,57,86,118] Hematopoietic stem cell transplant recipients should be revaccinated with a 3-dose regimen of Hib vaccine starting 6 to 12 months after successful cell transplantation, regardless of vaccination history; doses should be administered at least 4 weeks apart.[28,118] Children 12 through 59 months of age who have received either no doses or only 1 dose of Hib vaccine before 12 months of age should receive 2 additional doses of Hib vaccine 8 weeks apart; children who received 2 or more doses of Hib vaccine before 12 months of age should receive 1 additional dose. For children <5 years of age undergoing chemotherapy or radiation treatment who received Hib vaccine within 14 days of starting therapy or during therapy, repeat the dose or doses at least 3 months following therapy completion. A single dose of any Hib-containing vaccine should be administered to unimmunized (has not received a primary series and booster dose or at least 1 dose of Hib vaccine after 14 months of age) children and adolescents 15 months of age and older who are undergoing elective splenectomy; if possible, vaccine should be administered at least 14 days before the procedure. Unimmunized children aged 5 years old or older who have anatomic or functional asplenia (including sickle cell disease) and unvaccinated children 5 through 18 years of age with HIV infection should receive a single dose of any Hib-containing vaccine.[28,118]

Immunization is indicated in children with previous Hib disease during the first 2 years of life, in whom adequate immunity may not develop after infection, but it is not necessary in older children who have had Hib disease. These children should receive primary vaccination or revaccination with a second primary series beginning 4 weeks after the onset of disease.

Contraindications and Precautions

The only known common adverse events following administration of Hib vaccines are fever and local reactions, observed in <4% of recipients; serious reactions are uncommon.[119] The only contraindication to Hib vaccine is an anaphylactic reaction to a previous dose of the same vaccine.

Hepatitis B Vaccine

Between 2000 and 2014, the number of acute hepatitis B cases reported annually declined by 67%.[108,120] This steady decline coincides with implementation of a national strategy to eliminate transmission of HBV. The primary elements of this strategy are as follows: (1) screening of all pregnant women for HBV infection with the provision of postexposure prophylaxis to infants born to infected women; (2) routine vaccination of all infants and children <19 years of age; and (3) vaccination of others at increased risk for hepatitis B, including healthcare personnel (HCP), men who have sex with men, injection drug users, household and sexual contacts of people with chronic HBV infection, and adults with diabetes.[38,121–123]

In 2014, the incidence of hepatitis B cases among children and adolescents ≤19 years of age was 0.02 per 100,000 population, representing a 95% decline for that age group from 2000 to 2014.[120] During that time, the disparity between the population with the highest (black, non-Hispanics) and the lowest (whites) incidence has been reduced by approximately 90%. Among adults, 38% of cases occur in people in identified risk groups (i.e., injection drug users, men who have sex with men, and people with multiple sex partners), thus indicating a need to strengthen efforts to reach these populations with this vaccine.[38,120]

Recommendations for Immunization

Hepatitis B vaccine consists of purified HBsAg particles produced through recombinant DNA technology in yeast. Table 6.7 shows vaccine products that contain hepatitis B antigen and that are licensed in the US. This vaccine is usually given as a 3-dose series; doses 2 and 3 are administered 1 and 6 months, respectively, after the first dose. In the United States, monovalent hepatitis B vaccine is recommended as the first dose of the series for all newborns within 24 hours of birth if they are medically stable, born to HBsAg negative mothers, and ≥2000 g. Preterm infants weighing <2000 g and born to HBsAg-negative mothers should receive the first dose of vaccine 1 month after birth or at hospital discharge. Additional detail regarding hepatitis B vaccination of infants born to HBsAg-positive mothers or mothers whose hepatitis B status is unknown can be found in the ACIP hepatitis B recommendation (https://www.cdc.gov/mmwr/PDF/rr/rr5416.pdf). Alternative schedules include the following: 0, 1, 4 months; 0, 2, 4 months; and a schedule that includes 4 doses, with doses 2, 3, and 4 given at 1, 2, and 12 months, respectively, after the first. Schedules that vary the timing of the second and third doses to permit integration into the recommended childhood and adolescent immunization schedule have resulted in high immunogenicity. The final (third or fourth) dose in the hepatitis B series should be administered no earlier than 24 weeks after the first. A 2-dose schedule (second dose given 4 to 6 months after the first) has been approved for adolescents 11 through 15 years of age for a specific hepatitis B vaccine. Dosages vary by age, vaccine, and whether the child is born to an HBsAg-positive mother; dosages for infants and children are half of those required for adults. Minimal intervals between doses should be 1 month between the first 2 doses, and 2 months, but preferably 4 to 6 months or more, between the second and third doses; lapsed immunization does not necessitate restarting the vaccine series.[8] Three products that combine HBV vaccine with other vaccine antigens are licensed for use at various ages (see Table 6.7).

TABLE 6.7

Hepatitis B–Containing Vaccines Licensed in the United States

Vaccine	Antigen Content	Recommended Age Group
Recombivax HB	Hepatitis B	All age groups
Engerix-B	Hepatitis B	All age groups
Comvax[a]	Hepatitis B and Hib conjugate	6 wk–71 months

Pediarix	Hepatitis B + DTaP + IPV	6 wk–6 yr
Twinrix	Hepatitis B + hepatitis A	≥18 yr

[a] No longer manufactured; all doses of Comvax expired by August 19, 2016.

DTaP, diphtheria and tetanus toxoids and acellular pertussis; Hib, *Haemophilus influenzae* type b; IPV, inactivated poliovirus vaccine.

Response to a 3-dose series is excellent in all age groups; this series produces anti-HBV antibodies (anti-HBs) in 85% to 99% of recipients, and response is highest in children 2 through 18 years of age.[38,121] People with immunocompromising conditions, such as renal failure, have a poorer response, and higher doses are recommended. Vaccine efficacy measured in placebo-controlled trials in both high-risk children (infants of HBsAg-positive mothers) and adults has shown a short-term efficacy of 80% to 95%. Long-term follow-up of children and adults has demonstrated protection against serious consequences of infection (chronic carriage and chronic liver disease) in almost all people who show response to the initial series (anti-HBs level of ≥10 mIU/mL), but continued studies are needed. Booster doses of hepatitis B vaccine are not recommended for any age group; however, the need for a booster continues to be evaluated. HBV vaccine can be given simultaneously with all other childhood vaccines.

Contraindications and Precautions

Hepatitis B vaccination is contraindicated for people with a history of hypersensitivity to yeast or to any vaccine component. Despite a theoretical risk for allergic reaction to vaccination in people with allergy to *Saccharomyces cerevisiae* (baker's yeast), no evidence exists for adverse reactions after vaccination of people with a history of yeast allergy.

People with a history of serious adverse events (e.g., anaphylaxis) after receipt of hepatitis B vaccine should not receive additional doses. As with other vaccines, immunization of people with moderate or severe acute illness, with or without fever, should be deferred until the acute phase of the illness resolves. Immunization is not contraindicated in people with a history of multiple sclerosis, GBS, autoimmune disease (e.g., systemic lupus erythematosus or rheumatoid arthritis), or other chronic diseases.[69,70,121] Pregnancy is not a contraindication to vaccination. Limited data indicate no apparent risk for adverse events to developing fetuses when hepatitis B vaccine is administered to pregnant women.

Measles, Mumps, and Rubella Vaccine

Vaccination programs have reduced the incidence of disease caused by measles, mumps, and rubella viruses in the US.[37] Implementation of these strategies has resulted in interruption of measles transmission in the US and an all-time low number of 37 measles cases reported in 2004, 27 of which were imported and resulted in 6 secondary cases.[124] However, measles cases continue to occur in the US as a result of importation and transmission to mostly unvaccinated persons. In 2008, multiple outbreaks of measles occurred in the US, totaling 140 cases.[125] These cases resulted from importation into community clusters with large proportions of unvaccinated persons. Subsequently, in 2011, the US had 220 cases as more than 30 countries in the WHO European Region reported an increase in measles, and France was experiencing a large outbreak. Most of the cases that were brought to the US in 2011 came from France. The US reported 184 cases and 11 outbreaks in 2013.[126] In 2014, the US experienced 628 cases in 23 measles outbreaks, including a large outbreak of 383 cases, occurring primarily among unvaccinated Amish communities in Ohio. This total case count was the highest in the US since 1994. Many of the cases in the US in 2014 were associated with cases brought in from the Philippines, which experienced a large measles outbreak.[125,127] In 2015 the United States reported 189 measles cases, including many from a large, multistate measles outbreak linked to an amusement park in California. The outbreak likely started from a traveler who became infected overseas with measles and then visited the amusement park while infectious; however, no source was identified. Analysis by CDC scientists showed that the measles virus type in this outbreak (B3) was identical to the virus type that caused the large measles outbreak in the Philippines in 2014.[125]

From 1989 through 1991, there was a resurgence of rubella, primarily because of outbreaks among unvaccinated adolescents and young adults who initially were not recommended for vaccination and in religious communities with low rubella vaccination coverage. As a result of the rubella outbreaks, two clusters of approximately 20 CRS cases arose. Outbreaks during the mid-1990s occurred in settings where young adults congregated and involved unvaccinated persons who belonged to specific racial/ethnic groups. Further declines were observed as rubella vaccination efforts increased in other countries in the WHO Region of the Americas. From 2001 through 2004, reported rubella and CRS cases were at an all-time low, with an average of 14 reported rubella cases a year, four CRS cases, and one rubella outbreak (defined as three or more cases linked in time or place).[127a] In 2004, a 9-person independent panel unanimously agreed that rubella is no longer endemic in the US.[40] During 2004 to 2015, 99 cases of rubella and 9 cases of congenital rubella syndrome were reported in the US.[117a,128]

The incidence of reported cases of mumps in the US had been decreasing until 2006, when an outbreak involving several thousand people occurred.[129] Between 229 (in 2011) and 1057 (in 2015) cases of mumps have occurred.[130] Protection against measles, mumps, and rubella is provided by the combined MMR and MMRV vaccines.[8,73] Measles vaccine is a live, attenuated virus vaccine produced from the Moraten strain of measles virus, which was derived from the Edmonston B strain. Mumps vaccine is a live, attenuated vaccine derived from the Jeryl Lynn strain of mumps virus. Rubella vaccine is a live, attenuated vaccine derived from the RA27/3 strain of rubella virus that was grown on human diploid cells. Other rubella strains, with slightly different safety and efficacy profiles, were used in the US before 1979.

Recommendations for Immunization

A single dose of measles vaccine given to children ≥12 months of age induces antibody and produces protection in 95% to 98% of recipients. Protection is long-lasting, and waning of immunity, although documented in several studies, appears to be uncommon and plays a minimal role in measles outbreaks, which occur in the US because of importation and spread to unimmunized people.[73,124–127] Nevertheless, because infrequent vaccine failure with a single dose led to frequent measles outbreaks among schoolchildren, a second dose of MMR vaccine is now recommended for all children. In most studies, the second dose increases measles antibody response to >99%, whether the dose is given within 3 months of the initial dose or years later on a child's entry to primary or middle school. Additionally the booster dose can induce antibody increases in people with low levels of antibody, but the increases appear to be short-lived. Evaluation of actual clinical observational studies of measles vaccine effectiveness showed a median protection level of 93% for 1 dose and 97% after 2 doses.[73]

A single dose of mumps vaccine given at 12 through 15 months of age induces detectable antibodies in 80% to 85% of recipients. Median vaccine effectiveness has been estimated at 78% after 1 dose of vaccine and 88% after 2 doses.[73] Immunity is long-lasting, possibly lifelong, but waning immunity (or possibly primary vaccine failure) has been suggested as a contributing cause in some mumps outbreaks in highly vaccinated school populations. A large mumps outbreak that began in Iowa in December 2005 and spread to several other states prompted a change in recommendations for use of mumps-containing vaccines.[131] In addition to routine immunization, CDC recommends MMR vaccine for people born in 1957 or later who do not have a history of physician-diagnosed mumps infection, laboratory evidence of immunity, or immunity through vaccine, which the ACIP has redefined as 1 dose of mumps vaccine for preschool children and adults not at high risk, and 2 doses for children in kindergarten through 12th grade and adults at high risk (HCP, international travelers, and post high-school students).

During an outbreak, a second dose of mumps vaccine should be considered for all adults and children 1 through 4 years of age who have not received 2 doses; the second dose is given at least 28 days after the first dose. The CDC suggests that unvaccinated HCP born before 1957 who do not have other evidence of immunity also should receive 2 doses of the vaccine during an outbreak.

Currently, data are insufficient to recommend for or against the use of a third dose of MMR vaccine for mumps outbreak control. The CDC has issued guidance for considerations for use of a third dose in specifically identified target populations along with criteria for public health departments to consider for decision making. During mumps outbreaks, public health authorities may administer a third dose of MMR vaccine for specifically identified target populations. Criteria to consider prior to administering a third dose in a target *population for mumps outbreak control include:*

- *High two-dose vaccination coverage (i.e., vaccination coverage >90%)*
- *Intense exposure settings likely to facilitate transmission (e.g., schools, colleges, correctional facilities, congregate living facilities) or healthcare settings;*
- *High attack rates (i.e., >5 cases per 1,000 population); and evidence of ongoing transmission for at least two weeks in the target population (i.e., population with the high attack rates)*

Additional data on the effectiveness and impact of a third dose of MMR vaccine for mumps outbreak control are needed to guide control strategies in future outbreaks.[131a]

Rubella vaccine induces a primary response in 95% to 98% of children vaccinated at 12 months of age or older; protection is long-lasting, with >90% of recipients protected against clinical disease and viremia for >15 years. Median vaccine effectiveness has been estimated at 97% after 1 dose of vaccine.[73] In contrast to mumps and measles, in which vaccine failure has played a role in transmission, rubella vaccine failure has not played an important role in rubella outbreaks.

Vaccination to prevent measles, mumps, and rubella is recommended for all children and adolescents.[8,73] Measles vaccination and now mumps vaccine are recommended in a 2-dose series, given as MMR or MMRV, for all susceptible people. MMRV vaccine is indicated for simultaneous immunization against measles, mumps, rubella, and varicella among children 12 months through 12 years of age; MMRV is not licensed for people outside this age group.[73] For infants and young children, the first dose should be given at 12 through 15 months of age, and the second should be given at 4 through 6 years of age.[73] The timing of the first dose is based on the likelihood that maternal antibody does not persist during the second year of life; in the past, persistence of maternal antibody accounted for lower efficacy when vaccine was given at 12 through 14 months of age. Later studies have shown that younger mothers, who have acquired antibody through vaccination, may transfer less measles antibody to their infants (because vaccine induces lower titers than natural measles infection), who then become susceptible at a younger age.[132] During outbreaks that affect children <1 year of age (and for international travel to areas where measles is endemic), the age of measles vaccination should be lowered to 6 months; children vaccinated before 12 months of age still should be vaccinated with 2 doses of MMR or MMRV at the recommended ages.[73,133]

For dose 1 of the 2-dose MMR series, the risk of febrile seizures is increased in children who received MMRV compared with children who received simultaneous but separate MMR and varicella vaccines. For first dose at ages 12 through 47 months, either MMR and varicella vaccines or MMRV vaccine can be used. However, unless the parent prefers MMRV as a single injection, the CDC recommends that MMR and varicella vaccines should be given separately (but simultaneously) for the first dose. No evidence indicates an increased risk of febrile seizures with MMRV when it is used for dose 2 of the 2-dose series; MMRV is preferred over separate MMR and varicella vaccines for dose 2.[73]

Recommendations for timing of the second dose of MMR are based on (1) the major benefit of the second MMR in reducing the proportion of children who remain susceptible to measles because of failure of the primary vaccine and (2) the ease of implementation by using the preschool immunization visit. All children should be given the second dose of MMR vaccine at school entry if it was not given previously. The ACIP recommends that all children entering school have received 2 doses of MMR after the first birthday.[73] Receipt of 2 doses of MMR vaccine also is recommended for all people entering or enrolled in college; many states now implement prematriculation requirements, which have been shown to reduce the risk of measles outbreaks in these populations.

Rubella vaccination is recommended for all susceptible adults.[73] Adolescents and adults should be considered susceptible to rubella and should be vaccinated unless they have a history of ≥1 dose of vaccine or have serologic evidence of immunity. Ensuring rubella immunity is especially important in women of childbearing age. A clinical history of rubella is not sufficiently reliable. Delivery of rubella vaccine to adults is more successful in programs that do not use prevaccination screening because screening requires a second visit for susceptible people to be vaccinated.

Programs to ensure immunity to measles, mumps, and rubella are recommended for all HCP and for international travelers, who may be exposed to these diseases in countries with less effective control programs.[73] Among people born after 1956, measles immunity should be based on receipt of 2 doses of measles vaccine or serologic evidence of immunity. Acceptable presumptive evidence of immunity to mumps includes 1 of the following: (1) documentation of adequate vaccination; (2) laboratory evidence of immunity; or (3) birth before 1957. Evidence of immunity through documentation of adequate vaccination is now defined as 1 dose of a live mumps virus–containing vaccine for preschool-aged children and adults not at high risk and 2 doses for school-aged children (i.e., grades K through 12) and for adults at high risk (i.e., HCP, international travelers, and students at post–high school educational institutions).

Contraindications and Precautions

Measles, MMR, and MMRV vaccines produce minor reactions, including fever ≥39.4°C in 5% to 15% and transient rash in 15% of recipients. Fever and rash occur between 4 and 14 days after vaccination and last for several days. More serious reactions include febrile convulsions, in 1 in 3000 to 4000 recipients 1 to 2 years of age; the risk is higher in people with a personal or family history of convulsions.[73,134] Thrombocytopenia, which usually is transient, can occur in 1 in 30,000 recipients of MMR vaccine, and anaphylaxis, more rarely.[73] Three published reports of persons with immunodeficiencies described measles inclusion body encephalitis after measles vaccination, documented by intranuclear inclusions corresponding to measles virus or the isolation of measles virus from the brain.[73] The time from vaccination to development of measles inclusion body encephalitis for these patients was 4 to 9 months, consistent with development of measles inclusion body encephalitis after infection with wild measles virus. In 1 case, the measles vaccine strain was identified.[73] Available data do not support a relationship between measles-containing vaccine and subacute sclerosing panencephalitis (SSPE); in fact, widespread use of measles vaccines virtually has eliminated SSPE; no case of SSPE confirmed to be caused by vaccine virus has been reported.[67,69,73,135] The IOM rejected a hypothesized causal relationship between MMR vaccine and autism spectrum disorders.[70] Uncommon adverse events after mumps vaccines include aseptic meningitis, parotitis, orchitis, and low-grade fever. Reactions are expected to be less frequent among recipients of the second dose.

Adverse events after rubella vaccination include fever and mild rash in 5% to 10% of recipients, as well as joint pain, generally without arthritis. The frequency of arthritis increases with age of vaccination, particularly for recipients >15 years of age, and it can reach 40% in older women.[69,73] The rate of acute arthritis is lower than that observed for natural rubella in the same age group.[66,69] The IOM has concluded that evidence is insufficient to conclude that rubella-containing vaccines can cause chronic arthritis or arthralgia in children or adults.[69] Other studies have found no evidence for a risk of onset of chronic arthropathy after rubella vaccination, and a randomized trial found only a small risk of persistent joint pains.[136,137] The RA 27/3 rubella vaccine has not been linked to radiculoneuritis or neuropathy.

Vaccination with MMR or any component vaccine is contraindicated in pregnant women, in people with anaphylaxis from any vaccine component including neomycin or gelatin, and in people who are immunocompromised because of the following: (1) persons with primary or acquired immunodeficiency, including persons with immunosuppression associated with cellular immunodeficiencies, hypogammaglobulinemia, dysgammaglobulinemia, or AIDS or severe immunosuppression associated with HIV infection; (2) persons with blood dyscrasias, leukemia, lymphomas of any type, or other malignant neoplasms affecting the bone marrow or lymphatic system; (3) persons who have a family history of congenital or hereditary immunodeficiency in first-degree relatives (e.g., parents and siblings), unless the immunocompetence of the potential vaccine recipient has been substantiated clinically or verified by a laboratory; or (4) persons receiving systemic immunosuppressive therapy, including corticosteroids ≥2 mg/kg of body weight or ≥20 mg/day of prednisone or equivalent for persons who weigh >10 kg, when the drugs are administered for ≥2 weeks.[73] Rarely, disseminated infection and death resulting from measles encephalitis have been reported in immunocompromised people who were inadvertently given measles vaccine.[67,69] MMR or MMRV vaccination is indicated for people with asymptomatic HIV infection because measles can be severe in such people and vaccine can induce immunity; vaccination should be considered for symptomatic HIV-infected people if they do not have evidence of severe immunocompromise and they lack measles immunity.[28,86] Data show that even people with severe egg allergy can be vaccinated. Most anaphylactic reactions appear to be related to other vaccine components (e.g., gelatin).[138]

Rubella vaccine virus is able to cross the placenta and cause fetal infection; however, no case of congenital rubella syndrome resulting from vaccine virus was reported in infants of 680 susceptible women who received rubella vaccine within 3 months of conception and who carried their pregnancies to term.[73,139] The ACIP recommends that rubella vaccination not be considered a reason to interrupt pregnancy, but also that rubella vaccine not be given knowingly to a pregnant woman. A reasonable approach is to ask women whether they are pregnant now or may become pregnant within the next 28 days after immunization and to vaccinate only women who answer negatively.

Pneumococcal Conjugate and Polysaccharide Vaccines

Before the use of PCV7, *Streptococcus pneumoniae* was the most common bacterial cause of acute otitis media and invasive bacterial infections in children, with >17,000 cases of invasive disease occurring annually in the US in children <5 years of age. After the introduction of routine PCV7 immunization, the incidence of IPD declined dramatically, especially in children <2 years of age.[140–142] US population-based active surveillance data show that within 2 years of PCV7 licensure, the rate of IPD in children <2 years of age declined by 69%.[143] In tandem with the decrease in IPD, data suggest that the incidence of pneumococcal noninvasive disease in children, including otitis media, also decreased, as did antibiotic prescriptions.[144–146] In addition to decreasing the burden of pediatric pneumococcal disease, PCV7 may have had an impact on decreasing disease caused by *S. pneumoniae* in adults.[44–47]

In 2010, PCV13 was licensed. PCV13 contains the 7 serotypes included in the previously licensed PCV7 (4, 6B, 9V, 14, 18C, 19F, and 23F) and 6 additional serotypes (1, 3, 5, 6A, 7F, and 19A) each conjugated to cross-reactive material (CRM) 197, a nontoxic variant of diphtheria toxin. By 2008, 8 years after licensure of PCV7, 3 serotypes contained in PCV13 (3, 7F, and 19A) accounted for >90% of cases of IPD caused by the 6 additional serotypes.[140] PCVs induce a T-lymphocyte–dependent response that includes a primary response in infants and an anamnestic response to booster doses. Three doses of vaccine in infants induce significant increases in serum antibody concentrations to all 13 serotypes. PCV13 has reduced IPD across all age groups including adults since it has been used routinely in children in the US. These findings provide reassurance that, similar to PCV7, PCVs with additional serotypes can also prevent transmission to unvaccinated populations.[147,148]

Pneumococcal polysaccharide vaccine (PPSV23) consists of purified capsular polysaccharides of 23 serotypes of *S. pneumoniae,* which represented approximately 72% of strains isolated from cases of IPD in the US in immunocompromised children 6 through 18 years of age from 2007 through 2009.[149] PPSV23 vaccine induces increased antibodies to pneumococcal polysaccharides in 80% of healthy young adults after a single dose.[150] Initial studies showed high effectiveness in young, healthy adults; subsequent studies have shown approximately 60% effectiveness against IPD in adults at risk for disease but lower effectiveness in adults who are immunocompromised, who have cirrhosis or renal failure, or who are older.[151] Efficacy in children has not been measured, and the vaccine is not immunogenic in children <2 years. PPSV23 does not induce immunologic memory.

Recommendations for Immunization

Pneumococcal vaccination with PCV13 is recommended for all children <2 years of age.[140] The vaccine is given to infants as a 4-dose series at 2, 4, 6, and 12 through 15 months of age. Catch-up immunization is recommended for all children through 59 months of age, with fewer doses used depending on age. For high-risk children, catch-up is recommended through 71 months of age. Providers should give a dose of PCV13 to children at extremely high risk of invasive disease (functional or anatomic asplenia, immunosuppression [e.g., HIV infection], cochlear implant, and cerebrospinal fluid leaks), between the ages of 6 years and 18 years if they have not previously received PCV13.[149]

PPSV23 is given in a single dose to high-risk children ≥2 years of age.[140,149,150] PPSV23 is recommended for children at increased risk of pneumococcal disease irrespective of PCV receipt because PPSV23 provides protection against additional serotypes. One-time revaccination is recommended for people who are at highest risk of invasive disease (asplenia, immunosuppression, nephrotic syndrome) if 5 years have elapsed since the last dose. No more than 2 doses of PPSV23 are recommended. Children ≥2 years of age with high-risk conditions should first receive PCV13, followed by PPSV23 ≥8 weeks later (see Chapter 123).

Contraindications and Precautions

Adverse events after PCV13 administration are minor; examples are as follows: injection site erythema, swelling, and soreness, which occur in 35% to 49% of recipients; low-grade fever in approximately 40%; and higher fever (>39°C) in 5%.[140] Simultaneous administration of IIV and PCV13 has been associated with a transient increased risk of fever compared with administration of either vaccine alone in children 6 months through 4 years of age.[74,75,152] An increased risk of febrile seizures after simultaneous IIV and PCV13 administration was detected in the 2010 to 2011 influenza season, but not in the 2011 to 2012 and 2012 to 2013 seasons.[74] After evaluating data on febrile seizures from these 3 influenza seasons, and taking into consideration benefits and risks of vaccination, no policy change was recommended for use of IIV or PCV13. Surveillance for febrile seizures after IIV is ongoing through the VAERS.[74] No serious adverse events have been associated with use of PCV13. Use of PCV13 is contraindicated in people who have had anaphylactic reactions to a previous dose or to a vaccine component. Safety during pregnancy has not been evaluated. Systemic reactions to PPSV23 are uncommon, but mild local reactions occur in approximately one half of recipients and can be worse in people revaccinated within 5 years of initial vaccination.[140,150] PPSV23 vaccine is contraindicated in people who have had previous anaphylactic reactions to the vaccine or to vaccine components.

Poliovirus Vaccines

Through the use of OPV, the last case of indigenously transmitted poliomyelitis in the US occurred in 1979. In 2005 in the US, poliovirus infections occurred in 4 children who were not vaccinated for religious reasons.[153] All 4 children were asymptomatic and were infected with a poliovirus derived from viruses found in attenuated OPVs used in much of the world. In another report, an unimmunized 22-year-old woman acquired VAPP from a child immunized with OPV in Central America.[154] This was the first case of paralytic poliomyelitis identified in the US. since 1999 and the first imported VAPP case ever documented in the US. In 2008, a 44-year-old woman who was immunosuppressed because of common variable immunodeficiency acquired VAPP and died of complications of her chronic illness, including neurologic sequelae.[155] In 2013, an infant 7 months of age who recently immigrated to the US from India developed left leg paralysis after receiving OPV vaccination in India and was diagnosed with VAPP; further evaluation revealed the presence of severe combined immunodeficiency (SCID) syndrome.[156] These reports raise concerns about transmission of both vaccine-derived and wild polioviruses and the risk of a polio outbreak occurring in the US. Worldwide, poliomyelitis remains endemic in only 3 countries (Afghanistan, Nigeria, and Pakistan).[4]

Enhanced IPV is the only poliovirus vaccine now available in the US.[156a] IPV is derived from 3 wild strains of poliovirus (types 1, 2, and 3), which are inactivated by formalin. The quantity of antigen is measured in D antigen units, and IPV contains 40, 8, and 32 D antigen units for types 1, 2, and 3, respectively. Until 2000, when recommendations were made for exclusive use of IPV for routine immunization, live, attenuated OPV was available in the US. OPV is still the most commonly used poliovirus vaccine in the world. OPV is constituted from 2 Sabin strains of polioviruses (1 and 3), in concentrations of 1,000,000, 100,000, and 600,000 tissue culture infective doses ($TCID_{50}$) per vaccine dose, respectively.[157] Both IPV and OPV, when given as 3-dose primary series, induce protective antibody to each type of poliovirus in 95% to 99% of recipients. Antibody levels decline gradually, and booster doses of each vaccine are recommended at school entry. OPV induces higher levels of intestinal immunity than IPV and thus provides greater protection against infection because OPV better prevents replication and shedding of wild-type poliovirus in the intestine. In developing countries, OPV has lower per-dose effectiveness than in industrialized countries. Therefore, more doses are required to reach the immunity thresholds in the community to terminate transmission than would be needed in developed countries.

Vaccination against poliovirus is recommended for all children. With the progress in global poliomyelitis eradication and the continued risk of VAPP after OPV vaccination (approximately 8 cases per year from 1980 to 1994), the US vaccination policy was modified, first to a sequential schedule of 2 doses of IPV followed by 2 doses of OPV in 1997 and subsequently to a schedule of all IPV in the year 2000.[156a,158,159]

Recommendations for Immunization

IPV is recommended to be given at 2, 4, and 6 through 18 months of age, simultaneously with other childhood vaccines. Vaccination can be given at 6 weeks of age, and 4-week minimal intervals are acceptable for the interval between dose 1 and 2 and between dose 2 and 3.[156a] The interval between the next-to-last and last dose should be 6 months, and this booster dose is recommended at school entry and must be after the fourth birthday.[158] No need exists to restart the series if it is interrupted. OPV can be used in the same schedule, but OPV is no longer produced in the US and, for practical purposes, is no longer available. OPV continues to be the preferred vaccine in countries where poliomyelitis is or recently was endemic. However, with progress in global poliomyelitis eradication and the need to stop the use of OPV because it can rarely cause poliomyelitis, the Strategic Advisory Group of Experts (SAGE) of the WHO recommended that all countries add at least 1 dose of IPV to their immunization schedules.[2,156a,158,159]

Contraindications and Precautions

IPV is contraindicated only in children who have experienced a severe allergic reaction to a previous dose of IPV or to streptomycin, polymyxin B, or neomycin. OPV is contraindicated in children who have immunosuppressive conditions resulting from congenital immunodeficiency (agammaglobulinemia or hypogammaglobulinemia), cancer (leukemia or lymphoma), immunosuppressive chemotherapy, or AIDS.[28,156a] OPV also is contraindicated for family and other close contacts of immunocompromised people because of the risk of transmission of OPV to the affected person. Vaccination in pregnancy should be avoided on theoretical grounds, but, if necessary, IPV can be given.

No significant adverse reactions have been observed after administration of IPV. The major adverse reaction to OPV is VAPP, which develops at a rate of 1 in 2.5 million vaccine doses.[161] Before the policy change in the US, healthy vaccine recipients represented approximately 40% of cases of VAPP, contacts of recipients represented approximately 40% of cases, and immunosuppressed people represented 20%. The highest risk is associated with receipt of the first vaccine dose (1 in 700,000 recipients) and is 10-fold lower for subsequent doses. The risk in people with congenital immunodeficiency is approximately 2000-fold higher than in healthy recipients. The risk of VAPP appears to be raised by receipt of multiple doses of injectable antibiotics 1 to 30 days after immunization.[162] OPV rarely can cause disseminated infection and death in immunocompromised people.[67]

Varicella Vaccine

Live, attenuated varicella virus vaccine was licensed for use in US children and adults in 1995. By 2015, 92% of children 19 through 35 months of age were immunized with at least 1 dose of varicella vaccine.[163–164] Varicella vaccine, developed in Japan from the Oka strain of varicella virus, is >95% effective in protecting against severe disease with 1 dose and 85% effective against all varicella for children vaccinated at 1 to 2 years of age for at least 7 to 9 years after vaccination.[163a–165] Vaccinated children and adults who experience breakthrough infection with wild varicella-zoster virus usually have mild disease, with an average of <50 lesions (compared with >250 lesions observed in typical varicella).

Recommendations for Immunization

In 2006, the ACIP made policy changes for use of live, attenuated varicella-containing vaccines for prevention of varicella.[164] A routine 2-dose schedule of varicella vaccination of children is now recommended along with a second-dose catch-up varicella vaccination for children, adolescents, and adults who previously had received only 1 dose. The basis for these changes was as follows: (1) vaccine failures are recognized to occur after a first dose; (2) outbreaks of varicella had been reported in populations with high coverage with 1 dose of vaccine; (3) emergency revaccination during outbreaks, which previously had been recommended, was difficult and costly; and (4) evidence showed that a second dose could decrease vaccine failure rates and is associated with improved protection or efficacy. The ACIP also expanded recommendations for varicella-containing vaccines to promote wider use of the vaccine for adolescents, adults, and HIV-infected children and approved new criteria for evidence of immunity to varicella. Specific recommendations are as follows:

- All children <13 years of age routinely should receive 2 doses of varicella-containing vaccine, with the first dose administered at 12 through 15 months of age and the second dose at 4 through 6 years of age (i.e., before a child enters kindergarten or first grade). The second dose can be administered at an earlier age provided the interval between doses 1 and 2 is at least 3 months. However, if the second dose is administered at least 28 days following the first dose, the second dose does not need to be repeated.[8,164]
- A second catch-up dose of varicella-containing vaccine is recommended for children, adolescents, and adults who previously have received 1 dose, to improve individual protection against varicella and for more rapid impact on school outbreaks. Catch-up vaccination can be implemented during routine health provision visits and through school and college entry requirements. For persons age <13 years, a catch-up second dose can be administered at any interval ≥3 months after the first dose (see Figs. 6.2 and 6.3).[164] The minimum 3-month interval is the package insert allowance based on studies of the second dose. Future research may evaluate intervals as short as 1 month. The 2-dose varicella vaccination schedule is similar to the MMR vaccination schedule. MMRV vaccine is licensed and indicated for simultaneous vaccination against measles, mumps, rubella, and varicella among children 12 months through 12 years of age. MMRV is associated with an increased risk of febrile seizures following the first dose in people 12 through 23 months of age. Unless a parent prefers MMRV, separate simultaneous

administration of MMR and varicella vaccines is preferred to the combination vaccine for the first dose if the dose is given at 12 through 47 months of age. For second doses at any age or first doses administered at 48 months of age or older, the combination product generally is preferred, but providers need to consider the number of injections, the availability of vaccines, the timeliness of series completion, the potential of patients' return, storage and cost considerations, patients' choice, and the potential of adverse events. Students at all grade levels (including college) and children in childcare facilities should be protected against varicella.

HIV-infected children >12 months of age with $CD4^+$ T-lymphocyte counts of ≥15% of expected for age and without evidence of varicella immunity should be considered for vaccination with 2 doses of single-antigen varicella vaccine at a minimum interval of 3 months. Because data are not available on safety, immunogenicity, or efficacy of MMRV vaccine in HIV-infected children, MMRV vaccine should not be administered as a substitute for the component vaccines when vaccinating HIV-infected children.[164]

Women should be assessed prenatally for evidence of varicella immunity. On completion or termination of their pregnancies, women who do not have evidence of varicella immunity should receive the first dose of varicella vaccine before discharge from the healthcare facility. The second dose should be administered 4 to 8 weeks later (at the postpartum or other healthcare visit). To ensure administration of varicella vaccine, standing orders are recommended for healthcare settings where completion or termination of pregnancy occurs.[164]

Varicella vaccine previously was recommended for people ≥13 years of age without evidence of immunity who (1) have close contact with people at high risk for severe disease (HCP and family contacts of immunocompromised people) or (2) are at high risk for exposure or transmission. The ACIP now recommends that all people 13 years of age and older without evidence of immunity be vaccinated with 2 doses of varicella-containing vaccine at an interval of at least 4 weeks between doses or a second dose (catch-up dose) if they have received only 1 dose. The vaccine can be offered during routine healthcare visits.[164]

During a varicella outbreak, people who have received 1 dose of varicella vaccine should receive a second dose (including preschool-aged children who, according to the routine vaccination schedule, are recommended to have 1 dose of vaccine only), provided the appropriate vaccination interval has elapsed since the first dose (3 months for people 12 months through 12 years of age and at least 4 weeks for people ≥13 years of age).[164]

Revised criteria for evidence of immunity to varicella include any of the following: (1) documentation of age-appropriate vaccination (1 dose for preschool-aged children ≥12 months of age and 2 doses for school-aged children, adolescents, and adults); (2) laboratory evidence of immunity or laboratory confirmation of disease; (3) birth in the US before 1980 (although for HCP, pregnant women, and immunocompromised persons, birth before 1980 should not be considered evidence of immunity); (4) a healthcare provider diagnosis of varicella or a healthcare provider verification of history of varicella disease; and (5) a healthcare provider diagnosis of herpes zoster or a healthcare provider verification of a history of herpes zoster.[164]

Varicella vaccine can be given simultaneously with all other childhood vaccines. The vaccine also is recommended for postexposure prophylaxis of susceptible people up to 5 days after exposure to varicella and can be used for outbreak control.[164]

Contraindications and Precautions

Varicella vaccine induces mild varicelliform rash and fever in 5% to 10% of recipients.[164] Vaccine virus rarely can be transmitted from healthy people who experience rash. More serious adverse events (e.g., encephalitis, ataxia) have been reported rarely, at rates lower than expected after natural varicella and lower than background rates in the community. Varicella vaccine is contraindicated in people who have a blood dyscrasia, in people with primary or acquired immunodeficiency (including immunodeficiency from HIV infection), in pregnant women, and in people who have had an anaphylactic reaction to varicella vaccine or any component, including gelatin. However, vaccine can be given to people with humoral immunodeficiency and should be considered for people with asymptomatic or mildly symptomatic HIV infection with age-specific $CD4^+$ T-lymphocyte counts >15%, after the risks and benefits have been weighed.[164] As with measles-containing vaccines, vaccination should be delayed for ≥3 months after receipt of immunoglobulin or blood products because response to vaccine administered within this interval is unknown. Although varicella vaccine virus rarely has been isolated from patients with herpes zoster, the risk of clinical herpes zoster after varicella vaccination appears to be substantially lower among children than the risk after natural varicella infection.

Hepatitis A Vaccine

Hepatitis A childhood immunization has been implemented incrementally, starting with the ACIP recommendation in 1996 to vaccinate children living in communities with the highest disease rates and continuing in 1999 with the ACIP recommendations for vaccination of children living in states, counties, and communities with consistently elevated hepatitis A rates.[166,167] The strategy was expanded in 2005 to include routine vaccination nationwide of children 12 through 23 months of age.[168,169] In 2014, the incidence was estimated at 0.4 cases per 100,000, with 1239 cases reported.[120]

Recommendations for Immunization

Hepatitis A vaccines are produced in tissue culture and purified and inactivated with formalin; 2 vaccines have been licensed for use in the US since 1995.[169] These vaccines are highly immunogenic and are >95% effective in preventing HAV infection when given as a 2-dose series to children or adults.[169,171] Hepatitis A vaccine also can provide protection after exposure and can be useful in controlling hepatitis A outbreaks in well-defined populations. Hepatitis A vaccines are licensed for use in children ≥12 months of age.[169] A combination product consisting of hepatitis A and B vaccines given on a 0-, 1-, and 6-month schedule is licensed for people ≥18 years of age.

Hepatitis A vaccine is given as a 2-dose series, with doses separated by 6 to 18 months.[171] Recommendations for use of hepatitis A vaccine in children are as follows:

- All children should receive hepatitis A vaccine at 1 year of age (i.e., 12 through 23 months). Vaccination should be completed according to the licensed schedules and integrated into the recommended childhood immunization schedule. Children who are not vaccinated by 2 years of age can be vaccinated at subsequent visits.

- States, counties, and communities with existing hepatitis A vaccination programs for children 2 through 18 years of age are encouraged to maintain these programs. In these areas, new efforts focused on routine vaccination of children 1 year of age should enhance, not replace, ongoing programs directed at a broader population of children.
- In areas without existing hepatitis A vaccination programs, catch-up vaccination of unvaccinated children 2 through 18 years of age can be considered. Such programs may be warranted, especially in the context of increasing incidence or ongoing outbreaks among children or adolescents.

In addition, high-risk groups recommended to receive hepatitis A vaccine include men who have sex with men, users of illicit drugs, people with cirrhosis or clotting factor disorders, previously unvaccinated persons who anticipate close personal contact (e.g., household contact or regular babysitting) with an international adoptee from a country of high or intermediate endemicity during the first 60 days following arrival of the adoptee in the US, and people traveling to or working in countries where hepatitis A is highly endemic.[169,172]

Contraindications and Precautions

Adverse reactions to hepatitis A vaccine appear to be limited to pain at the injection site. The only contraindication to the vaccine is a severe reaction to a previous dose of the vaccine or to 1 of its components (alum or phenoxyethanol). Because hepatitis A vaccine is inactivated, no special precautions need to be taken when immunizing immunocompromised people.

Influenza Vaccines

Since the worldwide influenza pandemic of 1918 that caused an estimated 25 to 50 million deaths, the control of influenza circulation has been a major challenge to clinicians and public health experts. During 1976 to 2007, annual estimates of influenza-associated deaths from respiratory and circulatory causes ranged from 3349 (in 1986 to 1987) to 48,614 (in 2003 to 2004). During seasons when influenza A (H3N2) circulating strains were prominent, 2.7 times more deaths occurred compared with seasons when influenza A (H3N2) was not prominent.[173] The 2009 H1N1 influenza pandemic, which caused an estimated 12,469 deaths, renewed awareness of influenza.[174] Eighty-seven percent of the deaths occurred in people <65 years of age, with children and working adults having risks of hospitalization and death 4 to 7 times and 8 to 12 times greater, respectively, than estimates of impact from seasonal influenza covering the years 1976 to 2001. Additionally, influenza causes >200,000 hospitalizations annually.[175,176] Because of the frequent antigenic changes in influenza viruses, the antigenic content of influenza vaccine can be changed annually to optimize protection against influenza type A and B strains expected to circulate during the following winter and spring. Influenza viruses of type A (H1N1 and H3N2) and B are selected on the basis of immunologic match with circulating strains. Most vaccines in use in the US are made from viruses that are grown in chicken embryos and combined into a single vaccine containing components of all these strains. However, in recent years, vaccines grown in cell culture (ccIIV3) and made through recombinant DNA in baculoviruses have become available (RIV3). The efficacy of vaccine is related to the degree of match between the vaccine and circulating influenza viruses. Major antigenic drift in the circulating strain or strains is associated with seasonal epidemics because the population may have little immunity to the drifted strain from previous infection and the vaccine's effectiveness may be reduced substantially. Annual vaccination is necessary because immunity wanes over time and to optimize protection against each year's influenza strains.[177,178]

Recommendations for Immunization

Two types of influenza vaccines are licensed for use in the US: (1) IIV, which is either trivalent or quadrivalent, purified, split with a detergent, and inactivated with formalin; and (2) a quadrivalent cold-adapted, live, nasally administered vaccine (live, attenuated influenza vaccine [LAIV]). In 2010, the ACIP and AAP recommended expansion of annual influenza vaccination to all people 6 months of age and older. IIV can be used for all people without contraindications. In light of low effectiveness against influenza A(H1N1)pdm09 in the US during the 2013–2014 and 2015–2016 seasons, for the 2016–2017 season, ACIP made the interim recommendation that LAIV4 should not be used. Because LAIV4 is still a licensed vaccine that might be available and that some providers might elect to use, for informational purposes, reference is made to previous recommendations for its use. ACIP will re-review this decision in 2017.[179]

Some children 6 months through 8 years of age require 2 doses of vaccine. For 2015 to 2016, those who received ≥2 doses before July 1, 2015 required only 1 dose; for other children, 2 doses of vaccine, given at 4-week intervals, were recommended. For other groups, only a single dose is necessary. These guidelines can change each year, and so the most recent guideline should be consulted. All licensed influenza vaccines are included on a table published by the CDC that is updated whenever a new vaccine is licensed or a change in recommendations occurs (see http://www.cdc.gov/flu/protect/vaccine/vaccines.htm)

Contraindications and Precautions

IIV should not be administered to people known to have had a severe allergic reaction to any vaccine component, including egg protein. People with egg allergy who experienced only hives should receive influenza vaccine (IIV or RIV3) with in-office observation for 30 minutes.[180] People who report having had a severe reaction (e.g., anaphylaxis) can receive RIV3 if they are ≥18 years old, or they can receive IIV administered by a physician with experience in recognition and management of severe allergic conditions. Chemoprophylactic use of antiviral agents is an option for preventing influenza for persons who cannot receive vaccine.[181] Regardless of allergy history, all vaccines should be given in settings with the availability of appropriate resuscitative equipment. When vaccine supply is limited, efforts should focus on vaccinating those persons with conditions that put them at higher risk of influenza complications. The list of children and adolescents with high-risk conditions includes the following:

- Children 6 months through 4 years of age
- People who have chronic pulmonary (including asthma),

cardiovascular (except isolated hypertension), renal, hepatic, neurologic, hematologic, or metabolic (including diabetes mellitus) disorders

- People who are immunosuppressed (including immunosuppression caused by medications or by HIV)
- People who are or will be pregnant during the influenza season
- People who are 6 months through 18 years of age and are receiving long-term aspirin therapy and who therefore may be at risk for Reye syndrome after influenza virus infection
- Residents of nursing homes and other long-term care facilities
- American Indians and Alaska Natives
- People who are morbidly obese (body-mass index ≥40)

People with moderate to severe acute febrile illness usually should not be immunized until their symptoms have resolved. However, minor illnesses with or without fever do not contraindicate use of influenza vaccine, particularly among children with mild upper respiratory tract infection or allergic rhinitis.

Approximately 3% to 5% of recipients experience local tenderness or fever after vaccination. The occurrence of GBS within 6 weeks of influenza vaccination was observed in adults after the swine influenza vaccine program campaign in 1976 but was not observed subsequently until 1990, when a case-control study suggested a slightly elevated risk in persons 18 through 64 years of age but not in people ≥65 years of age.[177] Given the substantial benefits of influenza vaccination among the target populations, the risk of GBS, if any, is exceeded by the benefits.

LAIV should not be used in people of the following ages or with the following conditions: (1) age <2 years or ≥50 years, (2) those with contraindications listed in the package insert, (3) children 2 through 17 years old who are receiving aspirin or aspirin-containing products, (4) persons who have experienced severe allergic reactions to the vaccine or any of its components or to a previous dose of any influenza vaccine, (5) pregnant women, (6) immunosuppressed persons, (7) persons with a history of egg allergy, (7) children 2 through 4 years old who have asthma or who have had a wheezing episode noted in the medical record within the past 12 months or whose parents report that an HCP stated that they had wheezing or asthma within the last 12 months, and (8) persons who have taken influenza antiviral medications within the previous 48 hours. In addition to the groups for whom LAIV is not recommended, the "Warnings and Precautions" section of the LAIV package insert indicates that persons of any age with asthma may be at increased risk for wheezing after administration of LAIV and notes that the safety of LAIV in persons with other underlying medical conditions that could predispose them to complications after wild-type influenza infection (e.g., chronic pulmonary, cardiovascular [except isolated hypertension], renal, hepatic, neurologic, hematologic, or metabolic [including diabetes mellitus] disorders) has not been established. These conditions, in addition to asthma in persons aged ≥5 years, should be considered precautions for the use of LAIV.[179]

Meningococcal Vaccines

Rates of meningococcal disease have been declining in the US since the late 1990s. Fewer than 600 cases are now reported each year. In 2014, 433 invasive meningococcal cases were reported.[108] Meningococcal disease is seasonal: the number of cases generally peaks each year in January and February. The overall case-to-fatality ratio for meningococcal disease is approximately 10% to 15% and is somewhat higher in adolescents. Severe sequelae (e.g., hearing loss, neurologic disability, limb or digit loss, and skin scarring) occur in approximately 11% to 19% of survivors.[182] Infants have the highest rates of meningococcal disease, generally from serogroup B. Approximately three fourths of cases among adolescents and young adults are caused by serogroups B, C, or W. Serogroup A accounts for epidemics outside the US. Evidence demonstrates that college freshmen living in dormitories have historically had a modestly increased risk of meningococcal disease (4.6 cases in 100,000) compared with other people of the same age.[182]

Recommendations for Immunization

In the US, 4 meningococcal vaccines are licensed for use in children and adults against serogroups A, C, Y, and W, and 2 vaccines are licensed for people 10 years through 25 years of age against serogroup B.[182–184] A meningococcal polysaccharide (MPSV4) vaccine, containing antigens of serogroups A, C, W, and Y was licensed in the US in 1981 and was used until conjugated meningococcal vaccines were licensed.

By using the same technology used to develop PCV7, a meningococcal serogroup C conjugate vaccine was licensed in the United Kingdom in 1999. The vaccine was introduced into the routine infant schedule, with catch-up vaccination for older children and adolescents. In the 2 years after introduction of this vaccine, the incidence of serogroup C meningococcal disease declined by 87% in vaccinated people.[182] Substantial reductions in disease also occurred in unvaccinated populations as a result of community protection.

In the US, 3 MCVs are licensed for use. MenACWY-D (Menactra), a quadrivalent vaccine that includes serogroups A, C, W, and Y, is licensed for children from 9 months through 55 years of age. MenACWY-CRM (Menveo) includes the same 4 serogroups and is licensed for use from 2 months through 55 years of age. Hib-MenCY-TT (MenHibrix) contains meningococcal serogroups C and Y, in addition to Hib, and is licensed by the FDA as a 4-dose series for children 6 weeks through 18 months of age. These MCVs are recommended for use only in children <11 years of age who are at increased risk of meningococcal disease, including children with persistent terminal complement component deficiency, functional or anatomic asplenia, HIV infection, or during a community outbreak attributable to a vaccine serogroup (see Fig. 6.2).[59,59a] Each of the polysaccharides is linked to a diphtheria toxoid, CRM 197, or tetanus toxoid. Because MenACWY induces T-lymphocyte–mediated immunity and higher-quality immune responses, the duration of protection is thought to be longer than immunity produced by MPSV4.[182]

Current recommendations for use of MenACWY were published by the CDC in 2013 and 2014.[182,183] The first dose is recommended to be administered at age 11 to 12 years, and a booster dose should be administered at 16 years. A dose of MenACWY administered at 10 years of age can be counted as the 11- to 12-year dose. Doses administered before age 10 years are not counted as part of the routine adolescent MenACWY series. Adolescents who receive their first dose at 13 through 15 years of age should receive a booster dose at 16 through 18 years of age. The minimum interval between doses of MenACWY is 8 weeks. Adolescents who receive a first dose after their 16th birthday do not need a booster dose unless they become at increased risk for meningococcal disease. Persons 19 through 21 years of age are not recommended routinely to receive MenACWY. MenACWY can be administered up to age 21 years as catch-up vaccination for those who have not received a dose after their 16th birthday. HCP should use every opportunity to provide the booster dose when indicated, regardless of the vaccine brand used for the previous dose or doses. The minimum interval between doses is 8 weeks.

For people 9 months through 55 years old with HIV infection, persistent complement component deficiency, or asplenia (functional or anatomic), a 2-dose primary series should be given separated by 2 months. Routine booster doses should be given thereafter. If the most recent dose was received before 7 years of age, a booster should be administered 3 years later; otherwise, the interval is 5 years, with continued boosters every 5 years thereafter. For people without persistent complement component deficiency, and without asplenia (functional and anatomic), who may have received a first dose of MenACWY at 2 through 10 years of age (e.g., for international travel), the next dose should be administered at the following interval if the child remains at risk: after 3 years if the first dose was given at 2 through 6 years or after 5 years if the first dose was given at 7 years of age or older.[182]

Two meningococcal B vaccines have been licensed by the FDA for use in the US and approved for use in persons aged 10 to 25 years of age: MenB-FHbp (Trumenba, Pfizer, New York, NY) and MenB-4C (Bexsero, Novartis Vaccines). MenB-FHbp is licensed as a 2-dose series at 0 and 6 months. If the second dose is given <6 months after the first dose, a third dose should be given at least 6 months after the first dose; the minimum interval between the second and third doses is 4 weeks. MenB-4C is licensed as a 2-dose series, with doses administered at least 1 month apart, although in some studies, MenB-4C doses were administered up to 6 months apart. The 2 meningococcal B vaccines are not interchangeable; the same vaccine product must be used for all doses. The ACIP recommended that these vaccines be used for persons 10 years of age and older who are at increased risk of meningococcal disease, including (1) persons with persistent complement component deficiencies (including inherited or chronic deficiencies in C3, C5-9, properdin, factor D, factor H, or taking eculizumab [Soliris]), (2) persons with anatomic or functional asplenia (including sickle cell disease), (3) microbiologists routinely exposed to isolates of *Neisseria meningitidis,* and (4) persons identified to be at increased risk because of a serogroup B meningococcal disease outbreak.[184] The ACIP and CDC also have recommended that the serogroup B meningococcal vaccine series can be administered to adolescents and young adults 16 through 23 years of age to provide short-term protection against most strains of serogroup B meningococcal disease. The preferred age for MenB vaccination is 16 through 18 years.[185] The current low prevalence of disease, coupled with the lack of availability of important data for making policy recommendations for MenB vaccines, led the ACIP to determine that insufficient evidence exists to make a routine public health recommendation that all adolescents be vaccinated with MenB vaccine. Given the seriousness of meningococcal disease and the availability of licensed vaccines, the ACIP agreed that sufficient evidence exists to encourage individual clinical decision making.[185]

Precautions and Contraindications

Vaccination should be deferred for people with moderate or severe acute illness until their condition improves. MenACWY vaccination is contraindicated among people known to have a severe allergic reaction to any component of the vaccine, including diphtheria toxoid (for MenACWY), or to dry natural rubber latex. Because both MCVs are inactivated vaccines, they can be administered to people who are immunosuppressed as a result of disease or medications; however, response to the vaccine may be less than optimal.

To date, no randomized, controlled clinical trials have been conducted to evaluate use of MPSV4 or MenACWY vaccines in pregnant or lactating women. VAERS reports of exposure to MPSV4 or MenACWY-D during pregnancy have not identified adverse effects among either pregnant women or newborns of women vaccinated during pregnancy. Pregnancy should not preclude vaccination with MenACWY or MPSV4, if indicated. Women of childbearing age who become aware that they were pregnant at the time of MenACWY vaccination should contact their

HCP or the vaccine manufacturer so that their experience can be captured in the manufacturer's registry of vaccination during pregnancy.[182,186,187] The MenB vaccines are recommended by their manufacturers to be used during pregnancy only if clearly needed.[186,187]

Rotavirus Vaccine

Rotavirus is the most common cause of severe gastroenteritis in infants and young children worldwide. In developing countries, rotavirus gastroenteritis is a major cause of childhood death and is responsible for more than half a million deaths per year in children <5 years of age.[188,189] Before the routine use of rotavirus vaccines, rotavirus gastroenteritis resulted in relatively few childhood deaths in the US (approximately 20 to 70 per year). However, nearly every child in the US was infected with rotavirus by 5 years of age and most developed gastroenteritis, leading to >400,000 physician visits, >200,000 emergency department visits, 55,000 to 70,000 hospitalizations each year, and direct and indirect costs of approximately $1 billion.[189]

A live, attenuated tetravalent rotavirus vaccine prepared from rhesus rotavirus type 3 and human-rhesus reassortant types 1, 2, and 4 was licensed in 1999 for use in infants in the US. In prelicensure controlled trials, this vaccine was shown to be safe and highly effective, and it prevented >90% of hospitalizations for rotavirus diarrhea.[190] Following licensure, the vaccine was recommended for use in infants in March 1999. By June of that year, reports of adverse events suggested that cases of intussusception followed rotavirus vaccination. Subsequent studies demonstrated that children given this rotavirus vaccine had a relative risk of intussusception of 24.8 during the 3 to 7 days after the first dose, with an estimated risk of 1 case in 10,000 vaccinated infants.[32] On the basis of these data, the ACIP and AAP rescinded the recommendation for routine use of rotavirus vaccine in the US, and the manufacturer withdrew the vaccine from distribution.

The next generation of rotavirus vaccines licensed by the FDA includes 2 products. The ACIP states no preference between the 2 products. The first vaccine is a pentavalent reassortant vaccine (RV5, or Rotateq, Merck) that was licensed by the FDA in 2006. This vaccine is a live oral vaccine that contains 5 reassortant rotaviruses (G1, G2, G3, G4, and P1A) developed from human and bovine parent rotavirus strains.[191] Data from prelicensure trials showed immunogenicity of 93% to 100% and efficacy of 74% against rotavirus gastroenteritis of any severity and 98% against severe gastroenteritis.[192] The incidence of serious adverse events, intussusception, fever, and irritability was similar among RV5 and placebo recipients.[189,193] The second vaccine is a monovalent rotavirus vaccine based on an attenuated human rotavirus strain of P1A[8]G1 specificity, RIX 4414 (RV1, or Rotarix, GlaxoSmithKline Biologicals), licensed in 2008. This orally administered vaccine, given in 2 doses, has shown good clinical efficacy, and no increase in intussusception was noted among recipients of the vaccine versus placebo in a trial of >60,000 infants.[194,195] In postlicensure studies in Mexico and Brazil, RV1 prevented approximately 80,000 hospitalizations and 1300 deaths annually and was associated with a short-term risk of intussusception in approximately 1 in 51,000 to 68,000 vaccinated infants.[196] More recent studies in the US demonstrated a small increased risk of intussusception following rotavirus vaccination. Approximately 1 in 20,000 to 1 in 100,000 US infants who receive rotavirus vaccine may develop intussusception within a week of receiving the vaccine.[197,198]

Introduction of RV5 and RV1 has been associated with a dramatic reduction in rotavirus-associated hospitalizations, office visits, and overall burden of disease from rotavirus in the US.[199–203] In 2010, a virus or parts of a virus called porcine circovirus was found in both rotavirus vaccines. This virus does not cause disease in humans and is not thought to be a safety or efficacy concern.[204,205]

Recommendations for Immunization

All infants should be immunized routinely with 3 doses of RV5 administered orally at 2, 4, and 6 months of age or 2 doses of RV1 administered orally at 2 and 4 months of age. The first dose should be administered between 6 weeks and 14 weeks 6 days of age. Subsequent doses should be administered at 4- to 10-week intervals, and all doses of vaccine should be administered by 8 months 0 days of age. RV can be administered together with other childhood vaccines indicated at the same visits.

Premature infants (i.e., infants born at <37 weeks' gestation) can be immunized if they are at least 6 weeks of age, are being or have been discharged from the hospital nursery, and are clinically stable. Infants living in households with people who have or are suspected of having an immunodeficiency disorder or impaired immune status can be vaccinated, including infants living in households with pregnant women.

Readministration of a dose of RV to an infant who regurgitates, spits out, or vomits during or after administration of vaccine is not recommended. The infant should receive the remaining recommended doses of RV at appropriate intervals. If a recently vaccinated child is hospitalized for any reason, no measures other than routine universal precautions need be taken to prevent the spread of vaccine virus in the hospital setting.

Contraindications and Precautions

Contraindications for use of RV include a history of severe hypersensitivity to any component of the vaccine, a history of serious allergic reaction to a previous dose of vaccine, a history of intussusception, or a history of SCID.[206] SCID is a contraindication because 8 cases of SCID have been diagnosed in infants who received RV vaccine with evidence of gastrointestinal tract symptoms presumably caused by vaccine virus.[207,208]

Human Papillomavirus Vaccine

More than 150 types of papillomaviruses have been recognized on the basis of DNA sequence analyses, more than 40 of which infect the genital area.[209,210] HPV is associated with a variety of clinical conditions that range from benign skin and mucous membrane lesions to cancer. Clinical manifestations with the most frequently associated HPV types include skin warts (types 1, 2, 3, and 10), recurrent respiratory papillomatosis (types 6 and 11), condyloma acuminata (types 6 and 11), and cervical, anal, and oropharyngeal cancer (types 16, 18, 31, 33, 45, 52, and 58). The CDC estimated that approximately 30,700 new cancers were attributable to HPV annually between 2008 and 2012, including 19,200 among females and 11,600 among males.[208a] HPV is one of the most common causes of sexually transmitted infections in the US and worldwide, and it causes almost all the morbidity and mortality associated with cervical cancer.[209] Based on the association of HPV with cervical cancer and precursor lesions, HPV can be grouped into low-risk and high-risk HPV types. In the US and Europe, HPV-16 accounts for approximately 50% of cases of cervical cancer, with types 18, 31, and 45 accounting for an additional 25% to 30% of cases.[209,210]

Vaccination against high-risk HPV types could substantially reduce the incidence of cervical cancer. Administration of vaccine protecting against HPV-16 has been shown to reduce the incidence of HPV-16 infection and HPV-related cervical intraepithelial neoplasia.[211,212] In addition, a bivalent HPV vaccine was efficacious in preventing persistent cervical infections with HPV-16 and HPV-18 and associated cytologic abnormalities and lesions.[213] Three HPV vaccines are licensed in the US: (1) a 9-valent vaccine (9vHPV) containing virus-like particles of serotypes 6, 11, 16, 18, 31, 33, 45, 52, and 58; (2) a quadrivalent vaccine (4vHPV) containing virus-like particles of serotypes 6, 11, 16, and 18; and (3) a bivalent vaccine (2vHPV) containing virus-like particles of serotypes 16 and 18.[63,210] 2vHPV, 4vHPV, and 9vHPV all protect against HPV-16 and HPV-18, types that cause approximately 66% of cervical cancers and the majority of other HPV-attributable cancers in the US. 9vHPV targets 5 additional cancer-causing types, which account for approximately 14% of HPV-associated cancers in girls and women and 4% of HPV-associated cancers in boys and men. 4vHPV and 9vHPV also protect against HPV-6 and HPV-11, types that cause genital warts.

Recommendations for Immunization

HPV vaccination is recommended for girls, women, boys, and men. Routine HPV vaccination should be initiated at age 11 or 12 years but can be started beginning at age 9 years. Vaccination also is recommended for girls and women 13 through 26 years old and for boys and men 13 through 21 years old who have not been vaccinated previously or who have not completed the 3-dose series.[63] Men 22 through 26 years old can be vaccinated. Vaccination of girls and women is recommended with 4vHPV (as long as this formulation is available) or 9vHPV. Vaccination of boys and men is recommended with 4vHPV (as long as this formulation is available) or 9vHPV (see Fig. 6.2).

For persons initiating vaccination before their 15th birthday, the recommended immunization schedule is 2 doses of HPV vaccine. The second dose should be administered 6 to 12 months after the first dose (0, 6 to 12 month schedule). For persons initiating vaccination on or after their 15th birthday, the recommended immunization schedule is 3 doses of HPV vaccine. The second dose should be administered 1 to 2 months after the first dose, and the third dose should be administered 6 months after the first dose (0, 1 to 2, 6 month schedule).[210a] HPV vaccine can be administered at the same visit as other age-appropriate vaccines, such as Tdap and MCV4. Cervical cancer screening recommendations have not changed for girls and women who receive HPV vaccine because approximately up to 30% of cervical cancers are caused by HPV types not in the vaccine.[210]

HPV vaccine is not recommended for use in pregnancy. The vaccine has not been associated causally with adverse outcomes of pregnancy or adverse events to the developing fetus. However, data on vaccination in pregnancy are limited. A registry for girls and women inadvertently vaccinated during pregnancy was established by the manufacturer as part of its postlicensure commitment to the FDA.[210] More than 2800 girls and women who received vaccine within 1 month before their last menstrual period or anytime during pregnancy were enrolled in the registry. Rates of spontaneous abortions and major birth defects were not greater than those of a comparison unexposed population. The registry was terminated at the end of 2012 with concurrence from the FDA. The CDC will continue to monitor pregnancy outcomes through reports to the VAERS) and through studies in the Vaccine Safety Datalink. Any exposure to vaccine in pregnancy should also be reported to the relevant vaccine manufacturer (Merck: 800-986-8999; GlaxoSmithKline: 888-452-9622).

Both 9vHPV and 4vHPV vaccines are licensed for boys and men 9 through 26 years of age.[63,210] The 4vHPV vaccines has been shown to be effective for prevention of genital warts, and the 9vHPV vaccine is presumed to be similarly effective from immunobridging data.[214] These HPV vaccines have been licensed by the FDA for prevention of anal cancer and genital warts and are recommended for boys and men 11 through 21 years of age and for men 22 through 26 years of age who are immunosuppressed, have HIV infection, or are men who have sex with men. Either of these HPV vaccines can be given to boys 9 through 10 years of age and men 22 through 26 years of age at the provider's discretion.

Contraindications and Precautions

HPV vaccine is contraindicated for people with a history of immediate hypersensitivity to any vaccine component. Quadrivalent HPV vaccine is produced in yeast cells. Bivalent HPV vaccine is produced using a baculovirus-infected insect cell line. HPV vaccine can be administered to people with minor acute illnesses. Vaccination of people with moderate or severe acute illnesses should be deferred until after the illness improves.

Selected Other Vaccines That Can Be Used in Children and Adolescents

Bacille Calmette-Guérin Vaccine

A live, attenuated vaccine prepared from the Calmette-Guérin bacillus (bacille Calmette-Guérin [BCG]) strain of *Mycobacterium bovis* is intended to prevent serious *Mycobacterium tuberculosis* disease (tuberculosis [TB]).[215] The vaccine is used routinely throughout most of the developing world but only in restricted situations in the US. Data regarding the efficacy of BCG are highly variable and conflicting. Meta-analyses suggest that a single dose of BCG vaccine given at or soon after birth is approximately 50% effective in preventing the most severe outcomes of *M. tuberculosis* infection (disseminated or miliary TB).[215–217] Vaccine efficacy data in adults, such as HCP, are inconclusive. BCG vaccine can cause reactivity of the tuberculin skin test and thus reduce the test's utility for monitoring for *M. tuberculosis* infection and aiding in the decision whether preventive antimicrobial therapy is indicated.

In the US, BCG vaccine should be considered only for tuberculin-negative infants and children who continually are exposed and cannot be separated from adults who (1) are untreated or ineffectively treated for TB (if the child cannot be given long-term treatment for infection) or (2) have TB caused by strains resistant to isoniazid and rifampin.[215–217] Information about BCG vaccine can be found at www.cdc.gov/tb/publications/factsheets/prevention/BCG.htm/.

Vaccines for Travelers

Cholera Vaccine

A live, oral cholera vaccine, VAXCHORA, was licensed in the US in June, 2016. It is licensed for persons 18 through 64 years of age traveling to cholera-affected countries. VAXCHORA is a vaccine indicated for active immunization against disease caused by *Vibrio cholerae* serogroup O1. The effectiveness of VAXCHORA has not been established in persons living in cholera-affected areas, nor in persons who have preexisting immunity due to previous exposure to *V. cholerae* or receipt of a cholera vaccine. VAXCHORA has not been shown to protect against disease caused by *V. cholerae* serogroup O139 or other non-O1 serogroups (see http://www.fda.gov/downloads/BiologicsBloodVaccines/Vaccines/A for additional information). Two types of oral cholera vaccines are available in other countries: (1) Dukoral and (2) Shanchol and mORCVAX. The latter 2 are identical vaccines in terms of strains but are formulated by different manufacturers using different methods. Another cholera vaccine may be licensed soon in the US (see http://www.paxvax.com/cholera). These vaccines are not currently recommended for travelers.[218,219]

Japanese Encephalitis Vaccine

Japanese Encephalitis (JE) virus, a mosquito-borne flavivirus, is the most common vaccine-preventable cause of encephalitis in Asia. Among an estimated 35,000 to 50,000 annual cases, 20% to 30% of patients die, and 30% to 50% of survivors have neurologic or psychiatric sequelae. No treatment exists. For most travelers to Asia, the risk for JE is very low, but it varies on the basis of destination, duration, season, and activities.[220]

JE vaccine is recommended for travelers who plan to spend a month or longer in endemic areas during the JE virus transmission season and for laboratory workers with a potential for exposure to infectious JE virus.[220] The vaccine should be considered for the following: (1) short-term (<1 month) travelers to endemic areas during the JE virus transmission season if they plan to travel outside an urban area and will have an increased risk for JE virus exposure as a result of itinerary, activities, or accommodations; (2) travelers to an area with an ongoing JE virus outbreak; and (3) travelers to endemic areas who are uncertain of specific destinations, activities, or duration of travel. JE vaccine is not recommended for short-term travelers whose visit will be restricted to urban areas or times outside a well-defined JE virus transmission season.[220]

Inactivated Vero cell culture–derived JE vaccine (JE-VC [Ixiaro]) is the only JE vaccine licensed and available in the US.[220,221] JE-VC is licensed for use in adults and in children ≥2 months of age. The primary series consists of 2 intramuscular doses administered 28 days apart. For children 2 months through 2 years of age, each dose is 0.25 mL, and for adults and children ≥3 years of age, each dose is 0.5 mL. For persons ≥17 years of age, the ACIP recommends that if the primary series of JE-VC was administered >1 year previously, a booster dose can be given before potential JE virus exposure.[222] Data on the need for and timing of additional booster doses are not available. Data on the need for a booster dose following a primary series of JE-VC in children also are not yet available. An inactivated mouse brain–derived vaccine (JE-MB) previously was available and recommended for use in adults and children ≥1 year of age but is no longer being produced.

Typhoid Fever Vaccine

Two typhoid vaccines are available in the US: (1) a purified capsular polysaccharide parenteral vaccine prepared from the typhoid Vi antigen; and (2) an oral live, attenuated vaccine (*Salmonella typhi* Ty21a strain).[223,224] The inactivated Vi vaccine is given as a single dose, with booster doses at 2-year intervals if exposure continues. The oral vaccine is given as a 4-dose series of enterically coated capsules at 2-day intervals, taken before meals; the manufacturer recommends booster doses every 5 years if continued or renewed exposure to *Salmonella* serotype Typhi is expected. Both vaccines have efficacy of 50% to 80%. The minimal recommended ages for use of these vaccines are 2 years for the inactivated Vi vaccine and 6 years for the oral vaccine.

Typhoid vaccination is indicated for people who potentially will be exposed to contaminated food and water while traveling to areas in which typhoid is endemic (see http://wwwnc.cdc.gov/travel), for laboratory workers exposed to the organism, and for people exposed to typhoid carriers in the household. Inactivated Vi vaccine produces local reactions (swelling, induration) in 7% and fever or headache in fewer than 3% of recipients. Oral typhoid vaccine produces only minor adverse events, including nausea, vomiting, and abdominal discomfort. Oral typhoid vaccine should not be given to immunocompromised people (including people with HIV infection).

Yellow Fever

YF is a vector-borne disease transmitted to a human from the bite of an infected mosquito. YF is endemic to sub-Saharan Africa and tropical South America and is estimated to cause 200,000 cases of clinical disease and 30,000 deaths annually. Infection in humans is capable of producing hemorrhagic fever and is fatal in 20% to 50% of people with severe disease.[225] No treatment exists for YF disease. A traveler's risk for acquiring YF virus is determined by multiple factors, including immunization status, location of travel, season, duration of exposure, occupational and recreational activities while traveling, and local rate of virus transmission at the time of travel.

All travelers to countries in which YF is endemic should be advised of the risks for contracting the disease and available methods to prevent it, including use of personal protective measures and receipt of vaccine.[226] Administration of YF vaccine is recommended for people ≥9 months of age who are traveling to or living in areas of South America and Africa where a risk exists for YF virus transmission. Because serious adverse events can occur following YF vaccine administration, HCP should vaccinate only people who are at risk for exposure or who require proof of vaccination for entry into a country. To minimize the risk for serious adverse events, HCP should observe the contraindications, consider the precautions to vaccination before administering vaccine, and issue a medical waiver if indicated.[226] The YF vaccine is available in the US only from providers certified by state health departments (wwwnc.cdc.gov/travel/yellow-fever-vaccination-clinics/search.htm).

YF vaccine is contraindicated in people who have anaphylactic allergy to eggs, infants <6 months of age, and people with altered immune status as a result of a thymus disorder, immunodeficiency, or immunosuppressive or immunomodulating therapies.[226] Age 6 to 8 months and ≥60 years, asymptomatic HIV infection with moderate immunosuppression, pregnancy, and breastfeeding are precautions for YF vaccine administration. If travel to YF-endemic areas cannot be avoided or postponed for groups with a precaution for vaccination, the risk for YF virus exposure needs to be weighed against the possible risk for serious adverse events following vaccination.[226,227]

A single primary dose of YF vaccine provides long-lasting protection and is adequate for most travelers.[228] Additional doses of YF vaccine are recommended for certain populations (i.e., pregnant women, hematopoietic stem cell transplant recipients, and HIV-infected persons) who may not have as robust or sustained an immune response to YF vaccine compared with other recipients. Additional doses also can be given to certain groups believed to be at increased risk for YF disease either because of their location and duration of travel or because of more consistent exposure to virulent virus (e.g., laboratory workers).

Sources of Information on Vaccines

Important sources for information about vaccines are as follows:

Official Package Information Insert.

Manufacturers provide product-specific information for each vaccine; some of these are reproduced in their entirety in the *Physicians' Desk Reference.*

Centers for Disease Control and Prevention.

Specific information on immunization and vaccine-preventable diseases is available from the CDC website (www.cdc.gov/vaccines/) and the CDC Information Center (800-232-INFO [4636]).

Morbidity and Mortality Weekly Report.

This report, published weekly by the CDC, contains vaccine recommendations, reports of specific disease activity, policy statements, and regular and special recommendations of the ACIP.

Subscription information is available online at www.cdc.gov/mmwr/.

Health Information for International Travel.

Travelers' health information, including requirements and recommendations for specific immunizations and health practices for travel to various countries, can also be obtained through the CDC website (www.cdc.gov/travel) or the CDC information center (800-232-INFO [4636]).

American Academy of Pediatrics *Red Book: Report of the Committee on Infectious Diseases.*

The full report containing recommendations on all licensed vaccines, published by the AAP, is updated every 3 years. The most recent *Red Book* was published in 2015 and can be ordered from the AAP at www.aap.org/bookstore/ or 888-227-1770.

Control of Communicable Diseases in Man.

The American Public Health Association publishes this manual at approximately 5-year intervals. The 20th edition (2014) is available. The manual contains valuable information concerning the following: infectious diseases; their occurrence worldwide; immunization, diagnostic, and therapeutic information; and up-to-date recommendations on isolation and other control measures for each disease presented. The manual can be ordered at https://secure.apha.org/iMIS/APHA/Store.

Health Departments.

Most state and many local health departments provide routine immunizations, immunization cards, and schedules to patients. They also send out routine reports of disease incidence. Many states have print information online to be downloaded. State health department immunization websites can be found at http://www.cdc.gov/vaccines/imz-managers/awardee-imz-websites.html.

World Health Organization.

Additional information about the WHO and international vaccine programs can be found online at http://www.who.int/topics/vaccines/en/.

Gavi: The Vaccine Alliance.

Information on Gavi can be found at the website http://www.gavi.org/

Additional Useful Sources of Information.

Other resources include the following: the Immunization Action Coalition, online at www.immunize.org/; the National Network for Immunization Information, online at www.idsociety.org/; the Vaccine Education Center, online at www.chop.edu/service/vaccine-education-center/home.html; and the Institute for Vaccine Safety, online at www.vaccinesafety.edu.

Antimicrobial Chemoprophylaxis

John S. Bradley

Chemoprophylaxis is prevention of disease by administration of a drug. An antimicrobial agent is given to an individual who is at risk of developing an infection following exposure to bacteria, viruses, fungi, mycobacteria, or parasites, because of exposure to the pathogen. The term “prophylaxis” as used in this chapter does not apply to those situations in which infection is already established; however, for some children who already are infected, the term has been used in situations to denote the prevention of “disease” rather than infection. Other chapters discuss immunoprophylaxis (see Chapters 5 and 6) and barrier prophylaxis (e.g., use of condoms; see Chapters 51 and 52). Specific discussions of the prevention of travelers' diarrhea (see Chapter 8), neonatal conjunctivitis (see Chapter 80), malaria (see Chapter 271), and human immunodeficiency virus (HIV) infection (see Chapter 109) can also be found elsewhere. Similarly, immunoprophylaxis and chemoprophylaxis for immunocompromised hosts, such as solid-organ or bone marrow transplant recipients, or patients being treated for cancer, are not discussed specifically in this chapter.

Ideally, recommendations for antimicrobial prophylaxis should be based on data documenting efficacy in prospective, randomized controlled studies, but most prophylactic regimens are presumed to be efficacious on the basis of small clinical trials, supporting pharmacology and biologic plausibility. In addition, prophylaxis can be justified solely by the severe consequences of possible infection (e.g., infection of implanted neurosurgical or cardiac foreign material).

Chemoprophylaxis of infection in children can be classified as general or specific. Chemoprophylaxis is *general* when all children, regardless of underlying disease or other factors, are at substantial risk of infection following exposure to a pathogen (e.g., *Neisseria meningitidis* in households). Chemoprophylaxis is *specific* when it is administered to certain children who are deemed at special risk for infection because of the presence of an immunodeficient state or anatomic structural anomalies or because these children have undergone procedures or operations that can be associated with a risk of subsequent infection. Chemoprophylaxis should be administered during the entire interval of documented increased risk of infection; the duration of general or specific chemoprophylaxis varies. Prophylaxis can be short term, following a specific exposure (e.g., *N. meningitidis*), more prolonged with ongoing exposure (e.g., malaria), or administered over several years (e.g., rheumatic fever).

The benefits of chemoprophylactic strategies to decrease morbidity and mortality and their attendant costs to the healthcare system should be weighed against potential risks, including drug toxicities, costs, alteration of the host microbiome, and the development and spread of antimicrobial resistance. Every effort should be made to limit the duration of prophylaxis or to find alternative methods to prevent infection (e.g., clean intermittent catheterization of the urinary bladder to prevent urinary tract infections). Recommendations change periodically on the basis of evolving knowledge, changing pathogens, and susceptibility to antimicrobial agents. Updated guidelines for specific infections are published periodically by the Centers for Disease Control and Prevention, by the American Academy of Pediatrics,[1] in the *Medical Letter on Drugs and Therapeutics*,[2] by the American Heart Association,[3] and in peer-reviewed journals.

General Principles

For chemoprophylaxis to be effective, 3 criteria should be met:

1. The antimicrobial drug or drugs used must have activity against the likely infectious agent and attain appropriate tissue-specific drug concentration.

2. The host should have a well-defined increased risk of disease. Other important factors considered in assessing the need for prophylaxis are the likelihood of development of infection following exposure, the severity of infection with associated risk of morbidity or mortality, and communicability to others.

3. The safety of a chemoprophylactic agent must be such that complications of its administration do not outweigh the risks of infection (i.e., an acceptable risk-to-benefit ratio).

Chemoprophylaxis in Healthy Children

Chemoprophylaxis is recommended to prevent surgical and trauma-related infections (Table 7.1), as well as to prevent disease associated with significant morbidity and mortality caused by bacterial, viral, fungal, mycobacterial, and parasitic agents. Pathogen-specific chemoprophylactic agents, doses, and durations as well as alternative regimens are shown in Table 7.2.

TABLE 7.1

Classification of Operative Wounds and Risk of Infection

Classification	Criteria	Risk (%)
Clean	Elective, not emergency, nontraumatic; primarily closed; no acute inflammation; no break in technique; respiratory, GI, biliary, and GU tracts not entered	<2
Clean-contaminated	Urgent or emergency, otherwise clean; elective opening of respiratory, GI, biliary, or GU tract with minimal spill and not infected urine or bile; minor technique break	<10
Contaminated	Nonpurulent inflammation; gross spill from GI tract; entry into biliary or GU tract in the presence of infection; major break in technique; penetrating trauma lasting <4 hr; chronic open wounds to be grafted or covered	~20
Dirty	Purulent inflammation (e.g., abscess); preoperative perforation of respiratory GI or GU tract; penetrating trauma lasting >4 hr	~40

GI, gastrointestinal; GU, genitourinary.

TABLE 7.2

Chemoprophylaxis for Healthy Children Exposed to Specific Pathogens[a]

Pathogen or Disease	Prophylactic Agent	Dose/Day	Maximum Daily Dose	Divided Doses	Duration
Bordetella pertussis[b]	Erythromycin	40–50 mg/kg	2 g	4	14 days
	Azithromycin	10 mg/kg	500 mg	1	5 days
	or				
	Clarithromycin	15 mg/kg	1 g	2	7 days
***Haemophilus influenzae* type b**	Rifampin	20 mg/kg	600 mg	1	4 days
Corynebacterium diphtheriae	Erythromycin	40–50 mg/kg	2 g	4	7 days
	or				
	Benzathine penicillin	600,000 units (IM) if <30 kg 1.2 million units (IM) if ≥30 kg			Once
Neisseria meningitidis	Rifampin	20 mg/kg	1.2 g	2	2 days
	or				
	Ceftriaxone	125 mg (IM) if <12 yr 250 mg (IM) if ≥12 yr			
	or				
	Ciprofloxacin	500 mg if ≥18 yr	Once		
***Yersinia pestis* (pneumonic)**	Sulfonamide	40 mg/kg if <8 yr		2	7 days
	or				
	TMP-SMX	8 mg/kg TMP if <8 yr		2	7 days
	Tetracycline	15 mg/kg if ≥8 yr	1 g	4	7 days
Vibrio cholerae[c]					
<8 years	TMP-SMX	8 mg/kg TMP		2	3 days
8–17 years	Tetracycline	50 mg/kg	2 g	4	3 days
≥18 years	Ciprofloxacin	15 mg/kg	1 g	2	3 days
Streptococcus agalactiae	Ampicillin (maternal intrapartum)		2 g; then 1 g (IV) q4 h		Until delivery
	or				
	Penicillin G (maternal intrapartum)		5 million units; then 2.5 to 3 million q4h		Until delivery
***Mycobacterium leprae* (borderline or lepromatous)**	Dapsone	1 mg/kg	100 mg	1	3 yr
Herpes simplex virus[d]	Acyclovir (preemptive	60 mg/kg (IV)		3	10 days for preemptive

	following perinatal exposure for the neonate; see text)				
	Acyclovir (suppression of active infection in neonates with CNS infection; see text)	300 mg/m^2/dose		3 times/day	6 months
	Acyclovir (suppression of oral, genital or ocular infection)	10–20 mg/kg	800	2–4	Up to 12 months or longer
Influenza A[e]					
	Oseltamivir	By body weight, children ≥12 months: >40 kg: 75 mg; >23–40 kg: 60 mg; >15–23 kg: 45 mg Infants 9–11 months: 3.5 mg/kg Term infants 0–8 months: 3 mg/kg Preterm infants[f]	75 mg	1	See text
	Zanamivir inhaled (for prophylaxis for children ≥5 yr)	2 inhalations (5 mg per inhalation, 10 mg total per dose)	2 inhalations total	1	See text
Scabies	5% permethrin	Topically			Once
Neisseria gonorrhoeae					
Ophthalmia neonatorum	0.5% erythromycin	Topically			Once
Sexual exposure					Once
<45 kg	Ceftriaxone	25-50 mg/kg (IM)	125 mg		
45 kg and ≥8 years	Ceftriaxone plus	250 mg (IM)	250 mg		Once
	azithromycin	1 g orally in a single dose			
	or				
	Cefixime plus	400 mg			Once
	azithromycin	1 g orally in a single dose			
Chlamydia trachomatis					
<8 years	Erythromycin	50 mg/kg	2 g	4	7 days
≥8 years	Doxycycline	4 mg/kg	200 mg	2	7 days
	or				
	Azithromycin	1 g			Once
Treponema pallidum	Benzathine penicillin G	50,000 units/kg (IM)	2.4 million units (IM)	2	Once
	Alternative[a]				
	Doxycycline if ≥8 yr	4 mg/kg	200 mg		14 days
	Alternative				

	Azithromycin	2 g			Once
Klebsiella granulomatis	Doxycycline if ≥8 yr	4 mg/kg	200 mg	2	3 weeks
	or				
	TMP-SMX	8 mg/kg TMP	320 mg TMP	2	3 week

[a] Alternative drugs used only if other cannot be used; listings are not exhaustive. Some regimens are not of proven benefit. Administration is oral except as noted.

[b] See Chapter 162 for doses by age. Azithromycin dose for immunized at age ≥6 months is 10 mg/kg once followed by 5 mg/kg on subsequent 4 days (or maximum 500 mg, followed by 250-mg doses)

[c] Resistance of isolate requires revision of chemoprophylactic regimen.

[d] Based on current American Academy of Pediatrics recommendations for neonates and young infants.[13–14]

[e] Oseltamivir not recommended for routine prophylaxis for infants younger than 3 months of age because of the lack of safety data in that age group. Prophylaxis is indicated in very young infants when benefits outweigh possible risks.

[f] Oseltamivir dosing for preterm infants. The weight-based dosing recommendation for preterm infants is lower than for term infants. Preterm infants can have lower clearance of oseltamivir because of immature renal function, and doses recommended for full-term infants can lead to very high drug concentrations in this age group. Limited pharmacokinetic data provide the basis for once-daily dosing for prophylaxis of preterm infants using postmenstrual age (gestational age + chronologic age): 1.0 mg/kg per dose, orally, for those <38 weeks of postmenstrual age; 1.5 mg/kg per dose, orally, for those 38 through 40 weeks of postmenstrual age; 3.0 mg/kg per dose, orally, for those >40 weeks of postmenstrual age. For extremely premature infants (<28 weeks), please consult a pediatric infectious diseases physician.

CNS, central nervous system; IM, intramuscularly; IV, intravenously; SMX, sulfamethoxazole; TMP, trimethoprim.

Specific Pathogens With a Defined Point of Exposure

Neisseria meningitidis

The reported secondary attack rates for meningococcal disease among household contacts of index cases range from 0.25% in adults to 10% for infants younger than 1 year of age. Prophylaxis is reviewed in Chapter 125. Regimens using rifampin, ciprofloxacin, and ceftriaxone are effective in eliminating nasopharyngeal carriage of *N. meningitidis*.[4] The largest experience in children is with the use of rifampin. Prophylaxis should be instituted as soon as possible (preferably within 24 hours) for contacts in households and childcare centers, for close school contacts, as well as for persons who have had contact with infected oral secretions. Rifampin alters the metabolism of some drugs, including oral contraceptives, phenytoin, phenobarbital, carbamazepine, warfarin compounds, and other agents using the hepatic cytochrome P450 enzyme system. Safety of rifampin in pregnancy has not been established. Alternative agents include ceftriaxone and ciprofloxaxin.[4] Ceftriaxone requires injections, but compliance and antimicrobial exposure are ensured. Ciprofloxacin has been evaluated in adults and documented to eradicate carriage; fluoroquinolone agents have a relative contraindication in pregnant women, and prepubertal children out of concern for possible arthropathy. However, additional safety data on fluoroquinolones in children suggest that a single 10-day treatment course is unlikely to lead to long-term injury[5]; arthropathy is highly unlikely to occur with a single dose used for prophylaxis.

Haemophilus influenzae Type B

Prophylaxis against *Haemophilus influenzae* infections is discussed in Chapter 172. Infection caused by *H. influenzae* type b (Hib) is exceedingly rare in adequately immunized children. Rifampin is approximately 95% effective in the eradication of nasopharyngeal carriage of Hib in children.[6]

Group B *Streptococcus*

Early-onset disease caused by group B *Streptococcus* (*Streptococcus agalactiae)* can be prevented by intrapartum administration of ampicillin or penicillin[7] (see Chapter 119). Intrapartum administration of antibiotics does not prevent disease in infants who were infected before therapy was started, nor does it prevent late-onset group B *Streptococcus* infections.

Human Immunodeficiency Virus

Perinatal or intrauterine transmission of HIV is diminished by the administration of zidovudine and other anti-HIV retroviral therapy to the mother during pregnancy, with continued treatment of the infant for various periods of time after delivery, depending on the regimen used. This is an area of active investigation, and the most current information on treatment and prophylaxis is posted on the AIDSinfo website of the National Institutes of Health (http://aidsinfo.nih.gov/). Specific, current recommendations on regimens to prevent neonatal HIV infection can be found at: http://aidsinfo.nih.gov/ContentFiles/PerinatalGL.pdf. Current HIV maternal and neonatal prophylactic regimens with zidovudine and other agents or cesarean deliveries have reduced the rate of transmission in worldwide studies to <2% (see Chapter 109).[8] For recommendations for healthcare worker exposure[9] or sexual or injection-drug nonoccupational HIV exposure,[10] detailed antiviral drug recommendations based on risks of transmission balanced by risks of antiviral drug toxicity with chemoprophylaxis also are provided on the AIDSinfo website. The risk of HIV infection can be decreased after exposure, particularly if antiviral prophylaxis is provided within 12 to 24 hours of exposure (see Chapter 109).

Herpes Simplex Virus

Neonatal herpes simplex virus (HSV) infection usually results from exposure and transmission at the time of labor and delivery (see Chapter 204). With vaginal delivery during maternal primary genital infection, the rate of transmission of HSV to the infant can exceed 50%, whereas delivery during maternal reactivation disease carries a risk of less than 3% to 5%. It can be difficult to determine whether an active HSV infection is primary or recurrent because primary genital infection often is asymptomatic. Diagnostic tests for maternal HSV infection, including specific tests for HSV-1 and HSV-2, and rapid polymerase chain reaction testing for HSV DNA from mucosal surfaces, aid in defining the neonate's risk of infection, although many of these tests are not widely or rapidly available in hospitals to help with management decisions. For pregnant women, data on the efficacy of preventing infection by using antiviral prophylaxis with acyclovir or valacyclovir in patients with a history of genital HSV have prompted the use of antiviral agents during the last month of pregnancy. Prophylaxis can prevent recurrent infection at the time of delivery, although the impact of prophylaxis on preventing neonatal infection has not yet been demonstrated.[11,12]

For the neonate potentially exposed to a mother with recurrent genital HSV infection at the time of delivery, current guidance recommends cultures (e.g., cultures of the conjunctiva, mouth, nasopharynx, and rectum) and blood polymerase chain reaction at 12 to 24 hours of age in all infants who are asymptomatic without starting antiviral therapy,[13] whereas other experts consider that documented exposure to virus at the time of vaginal delivery constitutes sufficient risk to the infant to begin intravenous acyclovir therapy to prevent symptomatic infection. Positive results from culture specimens taken 24 hours or more after delivery are more likely to indicate infection, with a higher risk of developing symptomatic disease, thus leading the American Academy of Pediatrics to recommend intravenous acyclovir therapy when cultures are positive, to prevent symptomatic infection.[13]

For neonates with documented central nervous system HSV-2 infection, oral acyclovir prophylaxis to prevent symptomatic infection for the first 6 months of life has been associated with a modest benefit in improved cognitive development at 5 years of age, compared with children who did not receive prophylaxis.[14]

Acyclovir and valacyclovir prophylaxis to prevent recurrent symptomatic disease has been used to reduce the number of recurrent genital and oral-cutaneous HSV infections in adolescents and adults with frequent recurrences. In addition, acyclovir has been used prophylactically in children younger than 3 years of age who were exposed to HSV infections in daycare nursery outbreaks (30 to 60 mg/kg/day in 3 to 5 divided doses).[15] Some experts also recommend acyclovir prophylaxis following ocular HSV infections (recurrent HSV keratitis or recurrent infection of skin adjacent to the eye) to prevent corneal ulcerations and scarring. However, no data exist on the safety and efficacy of prophylaxis for children, and epidemiologic data document the increase in acyclovir resistance with long-term prophylaxis for keratitis[16] (see Chapter 295).

Respiratory Tract Bacterial and Viral Pathogens

Mycobacterium tuberculosis.

Isoniazid (INH) is effective in preventing symptomatic tuberculosis in latently infected asymptomatic children when the drug is given for 9 months (daily, or twice weekly with observed therapy), and INH is believed to be effective in preventing *Mycobacterium tuberculosis* infection in uninfected children following close exposure.[17,18] For children suspected of or documented to have latent tuberculosis infection caused by INH-resistant strains, rifampin should be administered for 4 months. Data suggest that a 12-dose, weekly administered regimen of combination of rifapentine and INH is as effective as INH alone, and this regimen has improved adherence compared with daily INH for 9 months.[19] Treatment of latent tuberculosis infection actually is therapy rather than prophylaxis because drug administration eradicates inapparent, ongoing latent infection and thereby prevents the progression to symptomatic disease (see Chapter 134).

Bordetella pertussis.

Macrolide agents are likely to be effective in preventing the transmission of *Bordetella pertussis* and in halting the development of clinical pertussis in household contacts before symptoms occur. Most *Bordetella* isolates are macrolide susceptible.[20–22] Both 5 days of azithromycin and 7 days of clarithromycin administration in older children and adults should be as effective as 14 days of erythromycin to prevent disease following exposure. Of the effective macrolides, azithromycin is the best tolerated and therefore the preferred agent. Given the association of idiopathic hypertrophic pyloric stenosis with administration of erythromycin to neonates, azithromycin also is the preferred agent for newborns. However, the safety profile of azithromycin in the newborn is not well defined, and cases of idiopathic hypertrophic pyloric stenosis following azithromycin have been reported. The risk for severe or fatal pertussis following exposure in neonates warrants administration of azithromycin, with close observation for the development of disease. Infants and children older than 2 months of age who are intolerant of macrolides should be given trimethoprim-sulfamethoxazole for 14 days as postexposure prophylaxis.

Influenza Virus.

Protection against influenza in high-risk patients, such as those with underlying cardiac or pulmonary disease, is best achieved by annual immunization. However, when this is not possible or is delayed, antiviral prophylaxis to prevent infection following an exposure until immunization can be completed is an appropriate strategy.[23,24] Prophylaxis should also be considered for immunocompromised children (for whom active immunization may not be protective) during periods of widespread influenza activity when exposures are likely. Neuraminidase inhibitors (zanamivir and oseltamivir) are effective for treatment and prophylaxis of both influenza A and influenza B virus infections. Although oseltamivir is approved by the Food and Drug Administration for treatment of infants 2 weeks of age and older, limited clinical information on safety exist for infants less than 3 months of age for whom prophylaxis is not recommended routinely.[23,25,26] Since 2005 to 2006, influenza A viruses have demonstrated widespread resistance to both amantadine and rimantadine, and influenza B virus is intrinsically resistant to these agents. Healthcare providers should follow annual recommendations by the Centers for Disease Control and Prevention and the American Academy of Pediatrics for optimal prophylaxis strategies, particularly for winter seasons in which vaccine strains of influenza are not well matched with circulating strains. Prophylaxis decreases but does not eliminate the risk of influenza infection.

Unusual Pathogens

Prophylaxis is recommended for several infrequent infections (see Table 7.2), including diphtheria, plague, cholera, and leprosy. Consultation with public health or infectious disease experts is recommended for dealing with these unusual infections in the United States.

Sexually Transmitted Pathogens

Prophylaxis is recommended after exposure to certain sexually transmitted agents. Despite the lack of evidence, prophylaxis is justified because (1) transmission rates of disease after exposure are high and (2) the diagnosis of infection can be difficult until active disease develops. Identification and treatment of index cases and contacts are critical to decreasing transmission in the community. Therefore, for certain infections that can be asymptomatic and for which transmission rates exceed 50%, such as gonorrhea, *Chlamydia* *trachomatis* infection, and syphilis, it is reasonable to provide therapy on an empiric basis, as outlined by the Centers for Disease Control and Prevention[27] (see Table 7.2). Guidelines also exist for evaluation and treatment of sexually abused children and adolescents[27] (see Chapter 54). Infants born to mothers who have untreated gonorrhea are at high risk of infection and should be given ceftriaxone, 25 to 50 mg/kg intravenously or intramuscularly once, not to exceed 125 mg; for premature infants and those with hyperbilirubinemia, ceftriaxone should be given cautiously because of concerns for bilirubin displacement from albumin binding sites caused by ceftriaxone. Additionally, ceftriaxone should not be administered concurrently with calcium-containing fluids because fatal calcium precipitation in the pulmonary vasculature can occur. No other regimens have been proven effective, and dual therapy with ceftriaxone and azithromycin is not currently recommended for newborns. If ceftriaxone cannot be used, please consult an infectious disease or public health specialist regarding the use of cefotaxime in neonates with gonorrhea.[27]

Chemoprophylaxis for Surgical Procedures and Trauma

Surgical procedures (see Chapter 100) and traumatic injuries (see Chapter 86) are associated with variable risks for infection. Studies documenting the efficacy of systemic prophylaxis of surgical wound infections have been performed primarily in adults, but the pathogenesis of such infections is assumed to be similar in children. The risk of infection can be estimated by categorizing the type of surgical procedure as clean, clean-contaminated, contaminated, or dirty, yielding a risk of infection from less than 2% up to approximately 40% (see Table 7.1).[28] Further assessment of risk is based on patients' characteristics.[29] Antibiotic prophylaxis is warranted in all patients who undergo procedures that are clean-contaminated, contaminated, or dirty (see Chapters 65, 66, 86, and 100).

Principles

During surgical procedures, the time of maximum risk of infection is relatively finite, and therefore chemoprophylactic regimens should be limited in duration. A single dose of antimicrobial agent given 60 minutes before the initial incision usually provides adequate tissue concentrations.[29–33] When an operation is prolonged, major blood loss occurs, or the agent used has a short half-life (e.g., 1 to 2 hours), additional dosage is advisable during the procedure.[29,32]

Surgical prophylaxis should be reserved for use in situations in which (1) the risks of infection outweigh the risks of toxicity of antibiotic therapy or the development of antibiotic resistance and (2) infection would have major consequence (e.g., when foreign material such as a ventriculoperitoneal shunt is implanted). The choice of antibiotic is based on its spectrum of activity against the most likely pathogens and the penetration at the site of interest. Periodic consensus recommendations for prophylaxis during surgical procedures are published by professional societies and in the *Medical Letter on Drugs and Therapeutics*.[2,29] Quality standards for prophylaxis in surgical procedures have been proposed.[34] Insufficient data exist on improved outcomes with the addition of vancomycin to standard preoperative regimens to prevent surgical site infections caused by methicillin-resistant *Staphylococcus aureus* (MRSA); routine use of vancomycin is therefore not recommended.[29] However, for selected patients known to be colonized with MRSA, particularly patients who are to undergo extensive operations and for procedures involving the placement of foreign material, preoperative skin decontamination should be performed, and anti-MRSA perioperative prophylaxis should be considered.[2,29]

Surgical Procedures

Neurosurgery.

Placement of a ventriculoperitoneal shunt is classified as a clean procedure. However, the morbidity associated with infection of ventriculoperitoneal shunts is high. A favorable role has been demonstrated for prophylactic antibiotic therapy.[29,35,36]

Head and Neck Surgery.

For clean-contaminated surgical procedures involving the head and neck, prospective studies in adults with cancer suggest that more prolonged antimicrobial therapy beyond 24 hours is not associated with lower infection rates.[37] A meta-analysis of studies investigating antimicrobial prophylaxis for tonsillectomy demonstrated decreased fever, but no consistent benefit in rates of secondary hemorrhage or pain.[38]

Noncardiac Thoracic Surgery.

Studies in adults undergoing chest procedures document a decrease in surgical site infections with antimicrobial prophylaxis.[29,39] Although documented rates of infection are lower with video-assisted thoracoscopic surgery compared with open procedures, prophylaxis also is recommended for video-assisted thoracoscopic surgery.[29]

Cardiac Surgery.

In cardiovascular surgery, antibiotic prophylaxis is the standard of care. Even with a small risk of perioperative infection, the high morbidity of infection has justified its use as currently proposed in surgical infection guidelines.[2,29,40–42] Antibiotic treatment for 24 hours is likely to provide maximum benefit with acceptable risks; treatment for longer than 24 to 48 hours is not likely to provide additional benefit. For operations that last longer than 400 minutes, patients who were given a second dose of cefazolin demonstrated a statistically significant decrease in infections compared with patients who were not (7.7% vs. 16%).[42]

A prospective study of antimicrobial prophylaxis during implantation of pacemakers in adults demonstrated a significant reduction in the incidence of infection.[43] Routine antimicrobial prophylaxis was recommended for all patients receiving cardiovascular implantable electronic devices in the 2010 American Heart Association guidelines.[44] Antimicrobial prophylaxis for placement of ventricular assist devices in adults has not been standardized or well studied, and wide variation in practice has been documented.[45] However, national guideline recommendations suggest that prophylaxis be used as for other cardiac procedures.[29]

Abdominal Surgery.

Many studies performed in adults document the efficacy of antimicrobial prophylaxis in abdominal surgical procedures, particularly for colorectal procedures and appendectomy when perforation has occurred.[29] Prophylactic agents should have activity against common flora of the gastrointestinal tract, especially gram-negative enteric bacilli and anaerobic bacteria. For an appendectomy for acute appendicitis (including ruptured appendix), a Cochrane meta-analysis demonstrated that prophylaxis improved outcomes compared with placebo.[46] However, for nonperforated appendicitis, a single preoperative antibiotic dose was as effective as either 24 hours or 5 days of antibiotic prophylaxis.[47]

Orthopedic Surgery.

Clean procedures that do not involve implantation of foreign materials do not require antimicrobial prophylaxis.[29] Prophylactic antibiotics (particularly antistaphylococcal agents) reduce the incidence of infection after several orthopedic procedures, particularly when foreign material (e.g., an artificial joint or internal fixation device with plates or screws) is implanted. Efficacy of prophylaxis has been demonstrated most strikingly in joint replacement procedures in adults.[48] Current regimens most commonly use single-dose or short-course (24 hours or less) cefazolin or a similar agent with good antistaphylococcal activity, with a caution to screen patients for MRSA colonization and if the patient is already known to be colonized or infected with MRSA, to use vancomycin prophylaxis.[2,29]

Genitourinary Surgery.

Prophylactic antibiotics are not routinely required for cystoscopy in a patient who does not have an indwelling catheter and whose urine is documented to be sterile, although in some prospective controlled trials in adults, the rate of bacteriuria following a procedure was decreased from 9% to 3% to 5% with antibiotic prophylaxis.[49] If the urine is not sterile or is not known to be sterile (e.g., a culture has not been performed), a single dose of prophylactic antibiotic is recommended before the procedure. If the procedure is more invasive and involves ureteroscopy or the implantation of prosthetic material, antibiotic prophylaxis also is recommended.[2,29]

Trauma

Traumatic injury has, understandably, a higher risk for infection than controlled surgical procedures, but the risk varies by the extremely heterogeneous types and locations of injury, as well as by the characteristics of penetrating injury and environmental contamination of the wound (see Chapters 86 and 88). Trials of prophylactic antibiotics after significant trauma have inconsistently demonstrated a benefit in preventing infection, but they cannot always adequately identify the population most likely to benefit. Practice guidelines have been created that stratify risk of open fractures by type of injury, and they appear to have successfully matched prophylactic antibiotic recommendations with risk.[50]

Mammalian Bite Wounds

Antimicrobial prophylaxis or early treatment of animal bite wound injuries is controversial (see Chapter 88). A meta-analysis of studies of antibiotic prophylaxis of mammalian bite wounds suggested a benefit for antibiotics when the bite was caused by a human and when the mammalian bite occurred on the hand.[51] High-quality, prospective comparative studies of antimicrobial prophylaxis in which the severity and location of the bite and surgical management are standardized are needed. Amoxicillin clavulanate in the 4:1 formulation (20 to 40 mg/kg/day of the amoxicillin component in 3 divided doses for 5 to 7 days) provides the best spectrum of activity for both animal and human bites, considering the most frequently responsible pathogens: *Pasteurella multocida* (in cat and dog bites), *Eikenella corrodens* (in human bites), anaerobic bacteria, streptococci, and *S. aureus.* Alternative prophylaxis could be needed if MRSA was known to have caused previous infections in the child with a bite, but no regimen has been studied.

Antimicrobial prophylaxis also is recommended following a dog or cat bite in patients who are immunocompromised or have asplenia, advanced liver disease, preexisting or resultant edema of the affected area, moderate to severe injuries (especially to the hand or face), or injuries that may have penetrated the periosteum or joint capsule.[52]

Chemoprophylaxis in Special Situations and in Children With Conditions Predisposing to Infection

Children predisposed to development of infection by virtue of an underlying condition, such as an immunodeficient state, or an underlying anatomic defect (congenital or acquired) may benefit from chemoprophylaxis (Table 7.3). Prophylaxis is required over a prolonged period of risk, and strict compliance with regimens is critical to preventing “breakthrough” infections.

TABLE 7.3

Chemoprophylaxis in Special Situations

Disorder	Prophylactic Agents	Doses	Duration
Previous RF	Benzathine penicillin G	1.2 million units every 4 wk (every 3 wk if high-risk)	RF without carditis: 5 yr after episode, or 21 yr of age, whichever is longer
	or		
	Penicillin V	250 mg twice daily	RF with carditis, without regurgitation (clinical or echocardiographic): 10 yr after episode, or well into adulthood, whichever is longer
	or		
	Sulfisoxazole	500 mg if ≤27 kg (60 lb); 1 g if >27 kg; once daily	
	or		
	Erythromycin	250 mg twice daily	RF with carditis, with regurgitation: 10 yr after episode, or at least 40 yr of age, sometimes lifelong
Asplenic states[a]	Penicillin V	125 mg twice daily if <5 yr 250 mg twice daily if ≤5 yr	At least until 5 yr of age or 5 yr after surgical removal, whichever is longer; see text
Recurrent otitis media	Sulfisoxazole	50 mg/kg at bedtime	3–6 months
	or		
	Amoxicillin	20 mg/kg at bedtime	3–6 months
Recurrent urinary tract infection	TMP-SMX	2 mg/kg TMP once daily	Variable
	or		
	Nitrofurantoin	1–2 mg/kg once daily	

Endocarditis	Standard:		
Dental, oral, or upper respiratory tract procedures	Amoxicillin (PO)	50 mg/kg (maximum 2 g) procedure; then 25 mg/kg 6 hr after initial dose	Once 30 to 60 min before the procedure
	Penicillin-allergic:		
	Clindamycin (PO)	20 mg/kg (maximum 600 mg)	
	Oral medication impossible:		
	Ampicillin (IM or IV)	50 mg/kg (maximum 2 g)	
	Cefazolin	50 mg/kg (maximum 1 g)	Once 30 to 60 min before the procedure
	or		
	Ceftriaxone (IM)	25–50 mg/kg (maximum 2 g)	
	or		
	Gentamicin (IM or IV)		2 mg/kg (maximum 80 mg) before procedure; can be repeated 8 hr after initial dose

[a] Asplenic states include congenital and surgical asplenia, and splenic dysfunction associated with hemoglobinopathies; also considered for persons with complement disorders. Vaccinations are also very important. See references 59 to 62.

IM, intramuscularly; IV, intravenously; PO, by mouth; RF, rheumatic fever; SMX, sulfamethoxazole; TMP, trimethoprim.

Previous Rheumatic Fever

Patients who have a well-documented history of acute rheumatic fever (including disease manifested by carditis, arthritis, or chorea) should receive continuous antibiotic prophylaxis to prevent recurrent attacks associated with either symptomatic or asymptomatic group A streptococcal infection. The preferred prophylactic agent is penicillin. To ensure adherence, monthly administration of benzathine penicillin (1.2 million units intramuscularly for children weighing more than 27 kg [60 lb]; 600,000 units for those weighing less than 27 kg) is recommended, but for patients believed to be compliant with oral therapy, continuous prophylaxis with penicillin V (phenoxymethyl penicillin), 250 mg twice daily, should be effective at preventing streptococcal infection if an exposure occurs. For patients receiving monthly intramuscular injections, adequate serum antibiotic levels may not persist beyond 3 weeks, and, in high-exposure situations, recurrences are less likely if intramuscular therapy is provided every 3 weeks rather than every 4 weeks.[53]

The appropriate duration of chemoprophylaxis for rheumatic fever is not known; some studies suggest that treatment can be discontinued in young adults who are at low risk for recurrent episodes of group A streptococcal infection.[54] Current recommendations for minimum duration are 5 years (or until age 21 years) for patients *without* carditis and 10 years (or until age 21 years, whichever is longer) for those *with* carditis, without residual heart disease. For patients with carditis *and* residual heart disease, prophylaxis should continue at least 10 years or until age 40 years (whichever is longer), with consideration given to lifelong prophylaxis[55] (see Table 7.3).

Recommendations for other conditions associated with *Streptococcus pyogenes* are less certain. Most experts recommend antibiotic prophylaxis for children with poststreptococcal Sydenham chorea, similar to that for rheumatic fever. Some experts recommend prophylaxis for 1 year in children who have had an episode of poststreptococcal reactive arthritis but have no evidence of rheumatic fever because reactive arthritis can be an incomplete manifestation of acute rheumatic fever. If no evidence of rheumatic fever is present after 12 months of prophylaxis, therapy can be discontinued, but the child with poststreptococcal reactive arthritis should be followed long term for new evidence of cardiac involvement.[55–58] The cost-to-benefit ratio, safety, and efficacy of prophylaxis of pediatric autoimmune neuropsychiatric disorders associated with streptococcal infection (PANDAS) have not been established; routine chemoprophylaxis is not recommended.

Asplenia

Children with functional or anatomic asplenic states, particularly sickle cell anemia, have been shown to benefit from continuous penicillin prophylaxis to prevent pneumococcal and other bacterial infections (see Chapter 106). A single prospective controlled study showed an 84% reduction in rate of infection in children younger than 3 years of age who received daily oral penicillin V (125 mg twice daily for children <5 years; 250 mg twice daily for children ≥5 years) compared with children receiving placebo.[59] A follow-up placebo-controlled trial of penicillin prophylaxis beyond 5 years of age in children who were receiving comprehensive care for sickle cell disease showed a low incidence of infection and no significant benefit of antibiotic prophylaxis in preventing pneumococcal bacteremia or meningitis (2% in the penicillin-treated group vs. 1% in the placebo group).[60] Prophylaxis can be discontinued in children older than 5 years of age, provided these children have not previously had invasive pneumococcal infection and are appropriately immunized for age with conjugate and polysaccharide vaccines.

Asplenia from other causes (congenital, surgical, functional) also is associated with an increased risk of fulminant septicemia. Compared with the incidence in healthy children, the incidence of mortality from septicemia is 50-fold higher after splenectomy for trauma (compared with >350-fold higher in children with sickle cell disease). Although the risk is higher in younger children and in the first 5 years after splenectomy, fulminant septicemia has been reported in adults more than 25 years after splenectomy.[61,62] The general consensus is that asplenic children with malignant disease, thalassemia, congenital anomalies, or other diseases with a high risk of fulminant infection should receive daily chemoprophylaxis.[61] Less certainty exists about the need for chemoprophylaxis in otherwise healthy children who undergo splenectomy for trauma. In general, prophylaxis (in addition to appropriate immunization) should be provided to asplenic children younger than 5 years of age and should be considered for older children. For children of any age, prophylaxis should be considered for 1 year after splenectomy.[61] Asplenic children should receive conjugate and polysaccharide pneumococcal vaccines, meningococcal conjugate vaccine (with appropriate boosting), and Hib vaccine, as recommended in Chapter 6.

Underlying Immunocompromising Conditions

The prevention of bacterial, viral, fungal, and mycobacterial infections in immune-compromised hosts is an area of active research. As new regimens for treatment of disease evolve, collaborative guidelines are published by professional organizations to aid the practitioner in decisions regarding prophylaxis for various high-risk populations, including children undergoing cancer chemotherapy,[63] stem cell transplantation,[64] solid-organ transplantation,[65,66] and therapy of HIV infection.[67]

Similarly, as primary immunodeficiencies of cellular or humoral immunity or of phagocytic cell function are increasingly identified and better characterized, a systematic approach to antimicrobial prophylaxis for each entity is considered, based on the expected pathogens and risks of infection (see Chapters 102 to 105).[68,69] Immunization with a protein-conjugate vaccine is likely to be more protective than antibiotic prophylaxis for those immunodeficiencies in which the child can mount an appropriate, protective response to immunization.

Other Underlying Conditions

Recurrent Otitis Media

The widespread use of conjugate pneumococcal vaccines has been associated with a decrease in the incidence of acute and recurrent otitis media. In the past, sulfisoxazole, amoxicillin, and trimethoprim-sulfamethoxazole were shown to be effective for prophylaxis in otitis-prone children, although not all placebo-controlled investigations documented benefit.[70–74] The development of colonization with antibiotic-resistant organisms, as well as transmission of these organisms to contacts (both adults and children), should be considered. No current studies of antibiotic prophylaxis have been performed in the current PCV13 era; therefore, the risks and benefits of tympanostomy tube placement and antimicrobial prophylaxis should be considered for each child based on factors such as age, frequency, and severity of infections.[75,76]

Urinary Tract Infection

Antibiotic prophylaxis is effective in preventing recurrent urinary tract infection and is indicated in children with underlying anatomic abnormalities or neurogenic bladder, which lead to a higher risk of infection, especially in patients with obstructive lesions or high-grade vesicoureteral reflex (grades III to V).[77–79] Prophylaxis is designed primarily to prevent incremental renal damage with each episode of pyelonephritis that may ultimately lead to renal failure later in life. In the past, children without the identifiable increased risk factors listed here who had recurrent infections also were believed to benefit from antibiotic prophylaxis. In this group, documentation of 3 or more urinary tract infections within a 1-year period was considered a reasonable indication for prophylaxis. The benefit of prophylaxis in this group is limited to decreasing the pain and discomfort that accompany urinary tract infections, rather than preventing renal scarring, although even this benefit was questioned in some well-controlled studies. Increased antimicrobial resistance is often associated with prophylaxis.[78,80–84]

Current American Urology Association guidelines for children suggest that more high-quality data are required before recommendations regarding antimicrobial prophylaxis can be made, particularly for specific high-risk groups of children who can benefit most from prevention of recurrent infections.[85]

Nitrofurantoin (1 to 2 mg/kg/day), and trimethoprim-sulfamethoxazole (2 mg/kg/day of the trimethoprim component) are the best-studied regimens in children for prophylaxis.

Prevention of Endocarditis

The American Heart Association periodically publishes guidelines for endocarditis prophylaxis. In 2007, major changes were made based on the Committee's conclusions: (1) extremely small numbers of cases of infective endocarditis would be prevented by antibiotic prophylaxis for dental procedures, even if prophylaxis were 100% protective; (2) prophylaxis should not be recommended solely on the basis of an increased lifetime risk of acquisition of endocarditis; (3) infective endocarditis prophylaxis for dental procedures should be recommended only for people with underlying conditions associated with the highest risk of adverse outcome from infective endocarditis; (4) for patients with these underlying conditions, endocarditis prophylaxis should be given for all dental procedures that involve manipulation of gingival tissue or the periapical region of teeth or perforation of the oral mucosa.[3] Antibiotic prophylaxis decreases the risk, but it does not always prevent the occurrence of endocarditis in high-risk children. Cardiac conditions associated with the highest risk of adverse outcome from endocarditis for which prophylaxis with dental procedures is recommended are shown in Box 7.1. Antibiotic prophylaxis is no longer recommended for any other form of congenital heart disease, including mitral valve prolapse with regurgitation, acquired valvulopathy, hypertrophic cardiomyopathy, or the presence of cardiac pacemakers or implanted defibrillators, unless the patient has a history of previous endocarditis or placement of a prosthetic valve. Antibiotic prophylaxis is not recommended for shedding of deciduous teeth or bleeding from trauma to the lips or oral mucosa.

Box 7.1

Prophylaxis for Infective Endocarditis According to Cardiac Conditions and Dental Procedures[3]

Cardiac conditions associated with highest risk of adverse outcome from endocarditis for which prophylaxis for dental procedures is recommended:

- Prosthetic cardiac valve
- Previous infective endocarditis
- Congenital heart disease[a]
    - Unrepaired cyanotic congenital heart disease including palliative shunts and conduits
    - Completely repaired congenital heart defect with prosthetic material or device, whether placed surgically or by catheter intervention, during the first 6 months after the procedure[b]
    - Repaired congenital heart disease with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device that inhibit endothelialization
- Cardiac transplantation in which cardiac valvulopathy has developed

Dental procedures for which endocarditis prophylaxis *is* recommended for patients above:

- All dental procedures that involve manipulation of gingival tissue or the periapical region of teeth or perforation of the oral mucosa
- Professional cleaning with gingival probing, biopsies, suture removal, placement of orthodontic bands

Dental procedures for which endocarditis prophylaxis *is not* recommended even for patients above:

- Routine anesthetic injections through noninfected tissue
- Taking of dental radiographs
- Drilling of carious teeth
- Orthodontic or prosthodontic procedures
- Placement or removal of appliances
- Placement of orthodontic brackets
- Adjustment of orthodontic appliances

---

[a] Except for conditions listed, antibiotic prophylaxis is no longer recommended for any other form of congenital heart disease.

[b] Prophylaxis is recommended because endothelialization of prosthetic material occurs within 6 months after the procedure.

From Wilson W, Taubert KA, Gewitz M, et al. Prevention of infective endocarditis: guidelines from the American Heart Association: a guideline from the American Heart Association Rheumatic Fever, Endocarditis, and Kawasaki Disease Committee, Council on Cardiovascular Disease in the Young, and the Council on Clinical Cardiology, Council on Cardiovascular Surgery and Anesthesia, and the Quality of Care and Outcomes Research Interdisciplinary Working Group. Circulation 2007;116:1736–1754.

The antibiotics recommended when prophylaxis is appropriate according to Box 7.1 are shown in Table 7.2. A single dose of antibiotic should be administered before the procedure. If the dose was inadvertently omitted, it can be administered up to 2 hours after the procedure.

Antibiotic prophylaxis is not recommended for routine noninvasive respiratory tract, genitourinary, or gastrointestinal procedures.[3] Antibiotic prophylaxis can be considered for patient with conditions listed in Box 7.1 who undergo an invasive procedure that involves incision or biopsy of the respiratory tract mucosa (e.g., tonsillectomy, adenoidectomy, bronchoscopy with incision of the respiratory mucosa) or when the procedure is performed to treat an established infection (e.g., to drain an abscess or empyema). For patients with conditions listed in Box 7.1 who are scheduled for cystoscopy or other urinary tract manipulation and who have an enterococcal urinary tract infection or enterococcal colonization, antibiotic therapy to eradicate or suppress enterococci in the urine before the procedure may be reasonable.[3]

Antibiotic prophylaxis is recommended for procedures on infected skin, skin structures, or musculoskeletal tissue only for patients with conditions listed in Box 7.1. In 2007, the American Heart Association reaffirmed previous recommendations of settings for which endocarditis prophylaxis is *not* indicated (including cardiac catheterization and cesarean delivery) and added the following procedures: ear and body piercing, tattooing, vaginal delivery, and hysterectomy.[3]

Protection of Travelers

Kevin L. Schwartz, Jay S. Keystone

More than 1.1 billion people, including an estimated 60 million children, travel internationally each year.[1–3] Up to 8% of travelers to developing countries seek medical care while abroad or on returning home.[4] Although travel can expose children to some risks, the benefits are many. A careful pretravel evaluation to provide appropriate guidance and preparation is critical to protect pediatric travelers and their families and allow them to enjoy their time abroad.

Preparation for Travel

General Advice

A pretravel evaluation should be performed at least 6 to 10 weeks before travel. The entire itinerary for the trip should be reviewed, including destinations, time and duration of travel, types of accommodation, activities, and potential exposure to insects and animals. The evaluation also should review the medical and immunization history of the child to ensure that appropriate advice is given regarding preventive measures, including necessary vaccines. This evaluation can be accomplished by providing a form for parents to complete and bring to the initial pretravel assessment visit. Particular attention should be given to children of immigrants who are returning to their home countries to visit friends and relatives (VFR) because these children have been shown to be at increased risk for many infectious diseases.[1,5,6] Many excellent resources, most of which are accessible online, provide pretravel advice for pediatricians (Box 8.1).

Travel health guidance should be provided regarding safety issues and infectious diseases.[7–9] Motor vehicle crashes are the most common cause of death among travelers; therefore, particular attention must be given to use of seat belts and car seats as recommended according to the age and size of the child.[10] Car seats may not be readily available at the destination and should accompany the family. Other injury concerns for children include drowning, falls from unprotected balconies or windows, and electrical injuries from unprotected outlets. Children and adolescents who participate in extreme sports and outdoor activities while traveling also should be informed of the potential risks. A parent traveling alone with children should have notarized documentation authorizing him or her to travel with the children.

Advice regarding food and water precautions and insect avoidance should be reviewed thoroughly. Skin protection is an important topic and includes both the risk of serious sunburn and the avoidance of infectious diseases. For sunblock, 30 is the minimum sun protection factor (SPF) recommended for children. Sunblock should be applied 30 minutes before exposure and always before insect repellent is applied where both are needed. Adolescent travelers should be counseled regarding safer sex practices and risks of body piercing and tattooing in less developed countries. Freshwater exposure of any kind should be avoided in areas that are endemic for schistosomiasis or where *Leptospira* species can contaminate the water. Exposure to infected stool of animals or humans can result in several types of parasitic infection either directly (e.g., hookworm) or through fecal-oral exposure (e.g., *Toxocara* spp.). Shoes provide more protection than sandals for children exposed to contaminated environments. Animal bites can result in injury, bacterial infection at the site, or rabies; therefore, children should be cautioned to avoid unknown animals while traveling. Because disposable diapers may not be available in some countries, parents should be aware that cloth diapers must be ironed after washing to kill eggs and larvae deposited on clothing by the tumbu fly, the vector of myiasis, in parts of Africa.

A travel medical kit should be assembled before travel and carried with the family at all times (Box 8.2). As at home, medications should be stored in childproof containers out of reach of children. A discussion of travel health insurance and what to do in the event of illness should be included in the evaluation. In addition, written material summarizing the pretravel advice can be helpful for families.

Box 8.2

Pediatric Travel Medical Kit

Nonprescription Items

- Personal information card: name, birth date, chronic medical conditions, regular medications, allergies, blood type, vaccination record, emergency contact information
- First aid supplies: bandages, adhesive tape, gauze, antiseptic cleaning solution, commercial suture or syringe kit (with letter from physician)
- Thermometer
- Analgesics or antipyretics: acetaminophen, ibuprofen
- Skin care products: sunscreen (sun protection factor [SPF] ≥30), barrier ointment/cream, topical corticosteroid cream, disinfectant solution (e.g., chlorhexidine)
- Antihistamine (e.g., diphenhydramine)
- Insect repellent (diethyltoluamide [DEET]), insecticide (permethrin)
- Water purification system
- Oral rehydration packets
- Antimotility agent (e.g., loperamide) if older child (≥2 years)
- Extra pair of prescription glasses

Prescription Items

- Currently prescribed medications
- Antimalarial prophylaxis
- Antibiotic for severe travelers' diarrhea (see text)
- Topical antibacterial ointment or cream

- Topical antifungal ointment or cream
- Topical ophthalmic and otic antibiotic solution

Immunizations Overview

Although immunization rates have been increasing in the United States, significant numbers of children are underimmunized.[11] Many countries with low immunization rates have ongoing transmission of vaccine-preventable illnesses that rarely are seen in North America. Consequently, children who travel must have up-to-date immunization coverage to minimize their risk of contracting vaccine-preventable diseases. Country-specific vaccine-preventable disease statistics and immunization schedules can be found on the World Health Organization (WHO) website, and a listing of international vaccine names also is available online.[12,13]

Travel vaccines are divided into the categories of routine, required, and recommended. *Required* travel vaccines are needed by travelers to cross international borders according to health regulations at the destination. Proof of yellow fever vaccination may be required for entry into or travel from countries where yellow fever is endemic. Vaccinations against meningococcus, influenza virus, and polio virus are required for travelers to the Hajj in Saudi Arabia.[14] *Recommended* travel vaccines include vaccines that should be considered according to the risk of infection during travel.

During the pretravel evaluation, some children may need to receive vaccines in the routine childhood and adolescent immunization schedule administered in an accelerated manner to complete their primary series, catch up with vaccinations, or complete the recommended pretravel vaccine series before departure (Table 8.1).[15–17] The routine or catch-up schedule for immunizations should be continued when the child returns.

TABLE 8.1

Acceleration of Routine Vaccine Schedule for Travel[a]

Vaccine	Earliest Age for First Dose	Minimum Interval Between Doses
Combined hepatitis A	1 yr	1 wk, 2 wk between second and third doses (booster after 1 yr)

and B[b]		
Hepatitis A	1 yr	6 months[c]
DTaP	6 wk	4 wk, 6 mo between third and fourth doses
IPV	6 wk	4 wk
OPV	Birth	4 wk
Hib (conjugate)	6 wk	4 wk (booster after 12 months of age)
Hepatitis B	Birth	4 wk, 8 wk between second and third doses (third dose should be given ≥16 weeks after first dose)
PCV13	6 wk	4 wk, 8 wk between third and fourth doses (after 12 mo of age)
Measles	6 mo followed by MMR at 12 mo and at 4 to 6 yr of age	4 wk
MMR	12 mo	4 wk
Rotavirus[d]	6 wk	4 wk
Varicella	12 mo	4 wk if ≥13 yr of age 3 mo if <13 yr of age

[a] Regular immunization schedule should be reinstituted on return from the endemic area.

[b] Combined hepatitis A and B accelerated schedule is an off-label use for children.

[c] Hepatitis A booster does not need to be given as an accelerated schedule because the seroconversion rate following the first dose is high. The second dose can be given any time after 6 months to induce long-lasting immunity.

[d] For rotavirus vaccine, the maximum age for the first dose is 14 wk and 6 days, and the maximum age for the last dose is 8 months and 0 days.

DTaP, diphtheria and tetanus toxoids and acellular pertussis; Hib, *Haemophilus influenzae* type b; IPV, inactivated poliovirus vaccine; MMR, measles, mumps, rubella; OPV, oral poliovirus vaccine; PCV13, 13-valent pneumococcal conjugate vaccine.

Two or more inactivated vaccines or an inactivated and a live vaccine can be administered simultaneously or at any interval. In general, 2 parenterally administered live vaccines should be administered either simultaneously or at least 28 days apart.[18] Caution must be used when scheduling live vaccine administration following immune globulin (IG) administration because decreased immunogenicity of the vaccines can result.[16] This is particularly true of measles and varicella vaccines. Measles- and varicella-containing vaccines should be deferred from 3 to 11 months after IG administration depending on the indication and dose of IG required (see Chapter 5). Although the effect of IG administration on the immunogenicity of varicella vaccine is unknown, the current recommendation is to use the same guidelines for varicella vaccine and IG as are used for measles-containing vaccines.[19] IG administration does not interfere with the immune response to yellow fever vaccine, oral poliovirus vaccine (OPV), rotavirus vaccines, or any inactivated vaccines. IG should not be given <14 days after administration of a live vaccine.

Routine Immunizations

Most North American vaccine-preventable diseases are endemic globally; therefore, a child's routine vaccination schedule should be brought up to date before travel.[15] In particular, the primary series of vaccines, including at least 3 doses of diphtheria and tetanus toxoids and acellular pertussis (DTaP) vaccine, should be administered by standard or accelerated schedules (see Table 8.1). The tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis (Tdap) adolescent preparation vaccine should be used as the adolescent booster beginning at 11 years of age.[20] People 7 through 10 years of age who are not fully immunized against pertussis should receive a single dose of Tdap. Tdap can be administered regardless of the interval since the last tetanus- and diphtheria-containing vaccine. Underimmunized children <6 years of age also should receive the conjugate *Haemophilus influenzae* type b (Hib) vaccine before travel.

Although global poliomyelitis eradication had been targeted for 2005, poliomyelitis remains endemic in 3 countries: Afghanistan, Nigeria, and Pakistan.[21] OPV, although widely used in the WHO Expanded Programme on Immunization-Plus (EPI-PLUS), is not available in the US. An accelerated schedule for inactivated poliovirus vaccine (IPV) should be initiated if required, with the first dose given at 6 weeks of age and subsequent doses given at least 4 weeks apart.[15] If a child is traveling in the first few weeks of life and OPV is available, vaccination with OPV can be initiated at birth, with subsequent doses at 4-week intervals.[17] A booster dose of IPV should be given at 4 to 6 years of age and at least 6 months following the previous dose.

Approximately 400 children die of measles every day; children <1 year of age have the highest risk of severe disease.[22] Suboptimal immunization rates raise the risk of transmission within the US, as evidenced by the 2015 outbreak linked to undervaccinated children at a California amusement park.[23] Moreover, the risk of subacute sclerosing panencephalitis is related to acquisition of measles virus at a young age. Maternal antibodies generally protect infants for <6 months. Children between 6 and 12 months of age who are traveling to countries where measles is endemic (including all countries where measles vaccination is not universal) should receive 1 dose of measles, mumps, rubella (MMR) vaccine before travel. Only doses given at or after 12 months of age count as part of the routine US immunization schedule. Children >12 months of age should receive 2 doses of MMR given at least 28 days apart before travel.

Hepatitis B is part of the routine immunization schedule in the US.[24] Children who have not completed their routine hepatitis B series should receive hepatitis B vaccine before travel to highly endemic areas. The hepatitis B series can be accelerated with doses given at 0, 1, and 2 months, followed by a fourth dose at 12 months. A hyperaccelerated schedule of 0, 7, and 21 days with a fourth dose at 12 months can be used if necessary. Although this schedule is not licensed by the US Food and Drug Administration, it is used widely in travel clinics. A 2-dose schedule of adult Recombivax HB (Merck, Whitehouse Station, NJ) at 0 and 4 to 6 months is licensed in the US for adolescents 11 through 15 years of age.[24]

Hepatitis A vaccine, recommended universally for US children, should be given as a 2-dose schedule beginning at 12 to 24 months of age with the second dose 6 months later.[25] Children who have not received the hepatitis A vaccine series should be vaccinated before travel to developing countries. Most hepatitis A cases imported into the US by travelers are related to travel to Mexico and Central America.[25] Although hepatitis A generally causes asymptomatic or mild infection in young children, such children can shed the virus for prolonged periods. Consequently, vaccination of young travelers is recommended to protect both the recipient and any contacts. Children from birth to <12 months of age who are at high risk of exposure to hepatitis A can be given 0.02 mL/kg of IG intramuscularly as passive hepatitis A prophylaxis.[25] For travel lasting longer than 3 months, a larger dose of 0.06 mL/kg should be used.

Twinrix (GlaxoSmithKline, Philadelphia) is a combined hepatitis A and B vaccine that is licensed for people ≥18 years of age.[17,24] Twinrix-Junior is not licensed in the US but is available widely in Europe and Canada for children 1 through 15 years of age. These vaccines are given in a 3-dose schedule at 0, 1, and 6 months. For last-minute travel they can be accelerated in a schedule of 0, 7, and 21 days with a booster given at 1 year.[26] In Canada and parts of Europe, 2 *adult* doses of the vaccine administered 6 months apart have been approved for children 1 through 15 years of age.[27,28]

Varicella vaccine is recommended for all susceptible children and is given in the US for children from 12 months through 12 years of age. For children <13 years of age, a second dose should be given 3 months after the first. For adolescents 13 years of age and older, 2 doses are required with an interval of at least 4 weeks between doses.[19]

The 13-valent pneumococcal conjugate vaccine (PCV13) is part of the routine childhood immunization schedule and should be given as a 4-dose series at 2, 4, 6, and 12 through 15 months of age, although the schedule can be accelerated (see Chapter 123).[29]

Two quadrivalent conjugate meningococcal vaccines for serogroups A/C/Y/W-135 (MCV) are licensed in the US for children. Menactra (Sanofi Pasteur, Swiftwater, Pa) is licensed as a 2-dose series between the ages of 9 and 23 months, whereas Menveo (GlaxoSmithKline) is licensed as a 4-dose series starting at 2 months of age. Both vaccines are recommended for persons at increased risk of meningococcal disease, including travelers to countries with hyperendemic or epidemic meningococcal disease.[30] In addition, MCV is recommended routinely for use in all children 11 to 12 years of age, with a booster dose at 16 years of age. Administer 1 dose at 13 through 18 years of age if the patient is not previously vaccinated (see Chapter 125).[31] As of January 2015, 2 novel vaccines for serogroup B have been approved in the US for persons 10 to 25 years of age in response to an outbreak in university students.[32] Bexero (GlaxoSmithKline) has been approved for use in Canada for children 2 months of age and older.[33] However, this vaccine is generally not recommended for travel unless someone is traveling to an area with an ongoing outbreak of serogroup B meningococcal disease.

Influenza vaccine is recommended for all people without medical contraindications 6 months of age and older.[34] The influenza season occurs from April to September in the southern hemisphere and year-round in the tropics. Influenza outbreaks have occurred on cruise ships and organized group tours in any latitude and season.[35]

Rotavirus vaccine is recommended for all US children starting at 2 months of age in a 2- or 3-dose schedule depending on which of the 2 licensed vaccines is used.[36] Rotavirus vaccine can be given in an accelerated dosing schedule, if needed (see Table 8.1).

Two human papillomavirus (HPV) vaccines are licensed in the US and Canada and are recommended for use in all girls at 11 to 12 years of age.[37] HPV4 vaccine is recommended for boys and girls at 11 to 12 years of age. HPV vaccines in children are administered in a 2- or 3-dose schedule, the second and third dose 2 and 6 months after the first dose or a single 6-month dose. The first dose can be given as early as 9 years of age.

Required and Recommended Vaccines for Travel

Table 8.2 provides details regarding travel vaccines recommended for children.

TABLE 8.2

Schedule and Dosing for Travel Vaccines

Vaccine	Schedule	Minimum Age	Dose (mL)	Route	Booster Dose
BCG (live, attenuated)	1 dose	Birth	<1 yr: 0.05 mL ≥1 yr: 0.1 mL	Intradermal preferred but subcutaneous acceptable	None
Hepatitis A/B, combined (inactivated/recombinant)	3 doses: 0, 1, and 6 mo	1 yr	0.5 mL	Intramuscular	None
Meningococcal A/C/Y/W-135 (conjugated polysaccharide)	2–6 mo = 4 doses: 0, 2, 4, 12 mo 7–23 mo = 2 doses: 0, 3 mo >23 mo = 1 dose	2 mo	0.5 mL	Intramuscular	<7 yr: 3 yr ≥7 yr: 5 yr
Rabies (inactivated cell culture)	3 doses: 0, 7, 21 or 28 days	Birth	1.0 mL	Intramuscular	Consider at 2 yr if high-risk
Typhoid, Ty21a (live, attenuated)	4 doses: alternate days	6 yr	1 capsule	Oral	5 yr
Typhoid, Vi (capsular polysaccharide)	1 dose	2 yr	0.5 mL	Intramuscular	2 yr
Yellow fever (live,	1 dose	9 mo	0.5 mL	Subcutaneous	10 yr

attenuated)					
Japanese encephalitis (inactivated cell culture)	2 doses: 0 and 28 days	2 mo	<3 yr = 0.25 mL ≥3 yr = 0.5 mL	Intramuscular	1 yr

BCG, bacille Calmette-Guérin.

Cholera Vaccine

The risk of cholera is low for travelers. Cholera vaccines are not available in the US. However, they are licensed in some countries: WC/rBS (Dukoral, SBL Vaccines, Solna, Sweden) and 2 closely related bivalent cholera vaccines Shanchol (Shantha Biotec, Hyderabad, India) and mORCVAX (Vabiotech Vietnam).[38] Dukoral is licensed for children ≥2 years of age. Cholera vaccine is not required for entry into any country. The WHO recommends use of cholera vaccine only for travelers at high risk such as emergency or relief workers who plan to work in refugee camps or as healthcare personnel in endemic areas.[39]

Typhoid Vaccine

Typhoid vaccine is recommended for pediatric travelers to the Indian subcontinent and other developing countries in Central and South America, the Caribbean, Africa, and Asia.[40] Children are particularly at risk of developing typhoid and of becoming chronic carriers. Two vaccines are available for prevention of typhoid: a live, attenuated oral vaccine (Ty21a), which can be used in children ≥6 years of age; and a purified Vi capsular polysaccharide vaccine that is delivered intramuscularly to children ≥2 years of age. The efficacy of both vaccines is approximately 50% to 70%; receipt of the vaccine does not eliminate the need for food and water precautions.[41–43] If exposure continues, revaccination is recommended every 2 years for the polysaccharide vaccine and every 5 years for the oral Ty21a vaccine.

The Ty21a vaccine is available only in capsules in the US, thus limiting usefulness in younger children. The Ty21a vaccine must be refrigerated and taken with cool liquids approximately 1 hour before eating. The Ty21a vaccine should not be taken concurrently with the antimalarial proguanil, and antibiotics should not be used from the day before the first capsule until 7 days after completing the vaccine course. Clinical trials of a Vi conjugate vaccine demonstrating safety, efficacy, and immunogenicity in infants and children are ongoing.[44–46]

Yellow Fever Vaccine

Yellow fever vaccine is a live, attenuated vaccine that may be required or recommended for travel to central South America and sub-Saharan Africa. Some countries in Africa require an international certificate of vaccination (or a physician's waiver letter) against yellow fever for all entering travelers; other countries may require evidence of vaccination for travelers coming from or traveling through endemic areas. The vaccine is recommended for all children ≥9 months of age traveling to endemic areas. A single dose of yellow fever vaccine confers lifelong immunity; therefore, boosters are not required for protection. However, a booster may be required every 10 years by some countries.[47] Risks and benefits of yellow fever vaccination and likelihood of infection must be considered carefully in pregnant women and in people who are immunocompromised.[48] Yellow fever vaccine contains egg protein; therefore, people with previous anaphylaxis in response to eggs should not receive the vaccine. The vaccine is only available in the US from providers certified by state health departments.[49]

A yellow fever vaccine–associated encephalitis syndrome has been reported in young infants at a rate of 0.5 to 4 per 1000 infants vaccinated.[17] Neurologic symptoms occur 7 to 21 days after immunization; disease is related to reversion of vaccine virus to wild-type neurotropic virus. Consequently, the vaccine is contraindicated in infants <6 months of age. For infants 6 to 9 months of age who cannot avoid travel to a yellow fever–endemic area, consultation with an expert in the field is recommended. Yellow fever vaccine–associated viscerotropic disease, a severe systemic illness that can result in fatal organ failure, rarely has been reported.

Rabies Vaccine

Rabies is highly endemic in Africa, Asia (particularly India, China, and Indonesia), and parts of Latin America, but the risk to travelers is low. Preexposure rabies immunization is recommended for travelers with an occupational risk of exposure, for people planning extended stays in endemic areas where medical care is limited, and for outdoor travelers.[50] However, studies suggest that animal bites often occur during short-term travel.[51] Given that children are more likely to interact with animals and not report an animal bite, rabies preexposure vaccination should be considered for children traveling to endemic countries for at least 1 month.[52] The preexposure vaccine is 3 doses of 1.0 mL each given intramuscularly at 0, 7, and 21 or 28 days.[50] The series can be administered using either of the 2 licensed vaccines in the US: human diploid cell vaccine (HDCV) or purified chick embryo cell vaccine (PCECV). If a vaccinated child is bitten or sustains a skin-penetrating scratch by a potentially rabid animal, the wound must be washed thoroughly, and 2 additional doses must be completed as soon as possible (given 3 days apart); rabies IG is not required.[53] Without preexposure immunization, rabies IG and 4 doses of an approved vaccine (given over 14 days) are required; however, rabies IG is often not available in many developing countries.[53]

Japanese Encephalitis Virus Vaccine

Japanese encephalitis, an arboviral infection transmitted by night-biting *Culex* mosquitoes, is endemic in rural areas of Asia, although occasional epidemics occur in periurban areas. In temperate regions, transmission occurs from April to November, but disease occurs year-round in tropical and subtropical areas. The disease is uncommon in travelers.[54] Although most cases are subclinical, half of patients with clinical disease have persistent neurologic abnormalities, and the case fatality rate is 20% to 30%.[54] The vaccine is recommended for all travelers who are traveling in endemic areas for at least 1 month. Vaccination also should be considered for shorter-term travelers with increased risk of Japanese encephalitis virus exposure. One Japanese encephalitis vaccine (JE-VC [IXIARO], Valneva Austria, Vienna, Austria, distributed by Intercell USA, Gaithersburg, Md) is licensed in the US for people ≥2 months of age.[54] Two doses of JE-VC are administered 1 month apart. For adults at ongoing risk of exposure, a booster dose of JE-VC is recommended at 1 to 2 years after the primary series.[54] For children, the duration of immunity is unknown.

Meningococcal Vaccine

Five serogroups of *Neisseria meningitidis* (A, B, C, Y, and W135) are responsible for most meningococcal disease. The epidemiology of serogroups responsible for disease is changing worldwide; B, C, and Y are most prevalent in the US, whereas A, C, and W135 cause most epidemic disease in sub-Saharan Africa. The incidence in the US is 0.3 cases in 100,000, and in sub-Saharan Africa it can be as high as 800 cases in 100,000 annually.[30,32]

Meningococcal vaccine is required for travelers to the Hajj and also is recommended for people traveling to the "meningitis belt" in equatorial Africa during the dry season from December to June, where serogroup A accounts for 85% of all cases. One of the quadrivalent conjugate vaccines for serogroups A/C/Y/W-135 (MCV4) can be given to children beginning at 2 months of age. Children who received the conjugate or polysaccharide meningococcal vaccine before 7 years of age should be revaccinated within 3 years if they remain at risk.[31] Novel serogroup B meningococcal vaccines have been approved for use in the US[32] and Canada.[33]

Tickborne Encephalitis Virus Vaccine

Tickborne encephalitis virus is transmitted by *Ixodes ricinus* ticks in the forests of central and eastern Europe during the summer months.[55] Two vaccines are licensed in Europe for use in children ≥1 year of age (FSME-IMMUN, Baxter Vaccine, Vienna, Austria; and Encepur, Novartis, Germany. According to CDC's *Yellow Book,* neither is licensed in the US.[3,43]

Bacille Calmette-Guérin Vaccine

Bacille Calmette-Guérin (BCG) vaccine is part of the routine vaccination schedule in many developing countries where tuberculosis (TB) is highly endemic. BCG does not prevent TB infection but has been shown to decrease the incidence of severe TB disease such as miliary TB and TB meningitis. Vaccination with BCG is generally not recommended in the US; however, it can be considered in selected children after consultation with a TB expert. In addition, children who do not receive BCG and who have traveled to a country with a high TB burden should have a tuberculin skin test before and 3 months after returning from travel.[56]

Malaria

Malaria is caused by infection with *Plasmodium* species, most commonly through the bite of an infected female *Anopheles* mosquito. Malaria is a leading cause of death among children <5 years of age worldwide, and it causes approximately 200 million infections and more than 500,000 deaths each year.[57] Young children, pregnant women, and people who previously have not been exposed to malaria have the highest risk of severe disease. Although malaria is endemic throughout the tropics, the highest risk for malaria infection in travelers occurs in sub-Saharan Africa, Papua New Guinea, the Solomon Islands, and Vanuatu.[52,58] No vaccine is available for prevention of malaria infection in travelers; therefore, families traveling with children must be provided with advice regarding personal protective measures and malaria chemoprophylaxis if they are traveling to endemic areas.

Chemoprophylaxis

The type of chemoprophylaxis recommended depends on the likelihood of drug resistance, potential adverse reactions, cost, and convenience. In addition, characteristics of the individual traveler, including age, ability to swallow tablets, and any specific contraindications, are relevant.[59] Breastfeeding infants require prophylaxis because antimalarial drugs do not reach high enough levels in human milk. Several medications are recommended for prevention of malaria in children: chloroquine, mefloquine, doxycycline, and atovaquone/proguanil.[59,60] Chloroquine is inexpensive and well tolerated, but it is of limited efficacy because of resistance to *Plasmodium falciparum* in all regions except parts of the Caribbean and Central America. Atovaquone/proguanil is typically the best tolerated, but it is the most expensive. It is approved for children >5 kg and comes as pediatric tablets. Mefloquine is safe for use in pregnancy and neonates and has the convenience of weekly dosing. Adult tablets need to be broken and compounded into a liquid. Neuropsychiatric side effects limit its tolerability, and increasing resistance is reported in Southeast Asia.[60] Doxycycline is contraindicated in children <9 years of age because of dental staining. Primaquine is recommended as a primary agent in areas with a high incidence of *Plasmodium vivax*, such as Central America, and as a second-line agent in other areas when other antimalarial drugs cannot be used (see Chapter 271).[61] Chloroquine should be initiated 1 to 2 weeks before travel and preferably 4 weeks before travel for mefloquine; doxycycline, atovaquone/proguanil, and primaquine can be started 1 day before exposure. Most chemoprophylactic agents must be continued for 4 weeks after departure from malaria-endemic areas except for atovaquone/proguanil and primaquine, which must be continued for only 1 week after exposure. However, in an atovaquone/proguanil prophylaxis study in 485 Israeli subjects, 87% discontinued the drug 1 day after travel; no cases of malaria occurred, suggesting a shorter duration after travel can be adequate.[62] Updated guidelines from national organizations such as the Centers for Disease Control and Prevention (CDC) and the Committee to Advise on Tropical Medicine and Travel (CATMAT) can be found online (see Box 8.1).

Protective Measures

Because no malaria chemoprophylaxis is 100% effective, personal protective measures, such as barrier and chemical protection and exposure avoidance, should be used to minimize risk of contact with mosquitoes. These protective measures also can decrease the risk of other vector-borne diseases, such as dengue and other arboviruses.

Because *Anopheles* species mosquitoes that transmit malaria bite from dusk to dawn, children must have adequate protection during these hours. The *Culex* species mosquitoes that transmit Japanese encephalitis virus also bite primarily between dusk and dawn, whereas the *Aedes* species mosquitoes that transmit dengue, chikungunya, and yellow fever viruses bite primarily during the day. When a risk of insect exposure exists, children should be dressed in light-colored clothing that covers their arms and legs. Other measures to avoid insect bites include staying in air-conditioned or well-screened accommodation or using insecticide-treated bed nets.

Chemical protection provides additional defense against insect-borne diseases. The safest and best studied is *N,N*-diethyl-meta-toluamide (DEET).[59] Although adverse reactions, such as encephalopathy and rashes, have been described with excessive or prolonged use of high concentrations of DEET in children, this compound is considered safe when used appropriately according to product label instructions (Box 8.3).[58,63] The concentration of DEET correlates with the duration of protection; therefore, products with lower concentrations must be reapplied. DEET is recommended by the American Academy of Pediatrics in concentrations up to 30% for children as young as 2 months of age; in standard preparations, this concentration provides 4 to 6 hours of protection.[64] Non–DEET-containing repellents such as picaridin, IR3535, and oil of lemon eucalyptus appear to be safe and well tolerated but must be reapplied more frequently.[61] Oil of lemon eucalyptus is not recommended in children <3 years of age.

Box 8.3

Precautions for Use of Diethyltoluamide

- Use repellents containing ≥30% DEET only.
- Apply sparingly to exposed skin.
- Apply only to intact skin.
- Apply to face by wiping; avoid eyes and mouth; do not spray directly on face.
- Wash off with soap and water when coming indoors.
- Do not inhale or ingest repellent.
- Do not apply on hands or other areas that are likely to come in contact with the eyes or mouth.
- Do not allow children younger than 10 years of age to apply DEET themselves. Apply to your own hands and then apply to the child.
- Do not use on children less than 2 months of age.

DEET, diethyltoluamide.

Permethrin (a safe chrysanthemum derivative) is a contact insecticide that can be used for treatment of bed nets and clothing.[60] Permethrin-treated fabric has a duration of efficacy between 2 weeks and 6 months depending on the method of treatment. The best chemical protection against mosquito bites is use of a combination of permethrin-treated clothing and an effective insecticide on exposed skin.

Travelers' Diarrhea

Travelers' diarrhea is one of the most common illnesses among travelers, and it affects 22% to 39% of children who travel.[65,66] Both the incidence and the severity of travelers' diarrhea are age dependent, with the highest rates, longest duration, and greatest severity occurring in infants and children younger than 3 years of age.[67,68] Children's stools normally can be quite variable; consequently, travelers' diarrhea is defined as a twofold or greater increase in the frequency of unformed stools, lasting at least 2 to 3 days. The infectious causes of travelers' diarrhea in children and adults predominantly are bacterial and include enterotoxigenic *Escherichia coli* (ETEC), which is the most common cause, enteroaggregative *E. coli* (EAEC), *Salmonella, Campylobacter, Shigella,* enteropathogenic *E. coli* (EPEC), and, rarely, shigatoxin-producing *E. coli* (STE). Viral and parasitic infections are less common causes of pediatric travelers' diarrhea, although rotavirus, *Cryptosporidium parvum, Giardia lamblia,* and *Entamoeba histolytica* also account for a small proportion of diarrhea cases in young travelers. Studies show that 15% or more of cases of travelers' diarrhea may be caused by norovirus.[69,70]

The risk of developing travelers' diarrhea depends on the travel destination, with rates as high as 73% among children traveling to North Africa and 61% among children visiting India.[67] Travel to Southeast Asia, Latin America, and other African countries has been associated with rates of approximately 40%. Although travelers' diarrhea generally is a self-limited infection, it can cause significant morbidity, particularly if it results in moderate to severe dehydration. Parents must be counseled regarding the symptoms and signs of dehydration, as well as the approach to oral rehydration and when to seek medical attention.[71]

Preventive Measures

Because no vaccines are licensed in the US for prevention of travelers' diarrhea in children, counseling regarding food and water precautions is the most important preventive measure. Vaccines are in development in preclinical and clinical phases against ETEC, *Shigella* spp., and *Campylobacter jejuni*. A cholera vaccine that also provides short-term protection against ETEC is licensed in Canada and Europe for children ≥2 years of age.[72]

General rules regarding food and water precautions when traveling apply to both children and adults; however, young children are more likely to explore the environment with their hands and mouths, thus creating opportunities for infection and increasing their risk of diarrhea.[52] Frequent handwashing with soap and water is critical, particularly before eating, although alcohol-based handwashes can be used when water is not available.

Children must be reminded to use safe water sources for all drinking, tooth brushing, and food preparation. Safe water sources include bottled water from a trusted source or water that has been boiled, chemically treated, or filtered. Combination chemical and filter pumps can provide the best protection because filters vary in the size of microbes that are removed.[73] Water should be boiled for at least 1 minute at altitudes <2000 m and 3 minutes at >2000 m.[56] Carbonated drinks also are considered safe for drinking, but water used to make ice can be contaminated. For infants, breastfeeding is the safest form of nutrition. In addition to its many health benefits, breastfeeding does not require a source of clean water, unlike the use of formula, both in its preparation and in the cleaning of bottles.

The selection and preparation of foods are important during travel to minimize the risk of travelers' diarrhea. Although the advice to "boil it, cook it, peel it, or forget it" frequently is given, this often is not practical to follow. If possible, only steaming-hot, freshly made food should be consumed. Families traveling with children should have a ready supply of snacks and avoid buying food from street vendors (Box 8.4).

Box 8.4

Prevention of Travelers' Diarrhea in

Children

Do

- Eat only thoroughly cooked food served hot.
- Peel fruit.
- Drink only bottled, carbonated, boiled, chemically treated, or filtered water.
- Prepare all beverages and ice cubes with boiled or bottled water.
- Wash hands before eating or preparing foods.
- Continue breastfeeding throughout travel period.

Do Not

- Eat raw vegetables or unpeeled fruit.
- Eat raw seafood or shellfish or undercooked meat.
- Eat food from street vendors.
- Drink tap water
- Consume milk or dairy products unless labeled as pasteurized or irradiated.

Additional food and water precautions can decrease risk of other infectious diseases while traveling. These include avoidance of unpasteurized dairy products to eliminate the risk of brucellosis and other bacterial infections. Raw or undercooked meat and fish should not be consumed because of the risk of parasitic infections. Avoiding undercooked seafood can decrease the risk of hepatitis A. In developing countries, raw vegetables and fruit that cannot be self-peeled should be avoided.

Chemoprophylaxis for travelers' diarrhea generally is not advised in children.[67] However, short-term prophylaxis (<3 weeks) could be considered for children with increased susceptibility to travelers' diarrhea, such as children with achlorhydria or children in whom travelers' diarrhea could have significant medical consequences (e.g., children with chronic renal failure, congestive heart failure, diabetes mellitus, or inflammatory bowel disease).[74]

Treatment

Treatment of travelers' diarrhea in children must include close attention to hydration status, and parents should be counseled regarding early signs of dehydration. Oral rehydration therapy using a homemade or commercially prepared oral rehydration solution (ORS) can be used to prevent dehydration associated with diarrheal disease. Commercial ORS should be used to treat mild to moderate dehydration; severe dehydration can require intravenous fluid resuscitation.[75,76] ORS packets should be part of a family's travel medical kit. Locally made preparations can be used early in therapy, although they differ in composition from the reduced-osmolarity ORS recommended by the WHO (Table 8.3).[75] For infants, breastfeeding should be continued, along with oral rehydration and solid food intake, although foods high in simple sugars should be avoided because the increased osmotic load can worsen fluid losses.

TABLE 8.3

Formulation of Oral Rehydration Solution

World Health Organization	Home Formula
NaCl 2.6 g/L (75 mmol/L sodium)	6 level teaspoons sugar
KCl 1.5 g/L (20 mmol/L potassium)	1/2 teaspoon salt
Trisodium citrate, dihydrate 2.9 g/L (10 mmol/L citrate)	1 L water
Glucose, anhydrous 13.5 g/L (75 mmol/L glucose)	A splash of lemon juice (for taste)

KCl, potassium chloride; NaCl, sodium chloride; $NaHCO_3$, sodium bicarbonate.

Loperamide generally is used in combination with antibiotics for treatment of travelers' diarrhea in adults; however, the role of loperamide in pediatric travelers' diarrhea remains controversial, even though this drug is licensed for use in children ≥2 years of age. Although loperamide has been shown to decrease the duration and severity of acute diarrhea in children, it has been associated with significant side effects in children and is not recommended for children <3 years of age.[76–78] Zinc supplementation has been associated with improved outcomes in diarrheal disease in children in developing countries, but zinc supplementation is not recommended in treatment of travelers' diarrhea.[76]

Empiric treatment with antimicrobial agents can be considered in pediatric travelers' diarrhea. However, treatment should be confined to moderate to severe diarrhea, given data that show a marked increased carriage of extended spectrum β-lactamase (ESBL)–producing Enterobacteriaceae with antibiotic use.[79] Azithromycin often is used as the first choice for treatment of pediatric travelers' diarrhea, especially in areas with a high prevalence of fluoroquinolone-resistant *Campylobacter* species (e.g., South and Southeast Asia), because the drug is given once a day and has a known safety profile in children. A dose of 10 mg/kg once daily for 3 days (maximum dose of 500 mg) is appropriate.[67] In adults, a single dose of antibiotic has been shown to be as effective as 3 days of treatment; therefore, in children a full 3-day course may not be necessary.[80,81]

Fluoroquinolones for 1 to 3 days are the drug of choice for adults with travelers' diarrhea that is moderate to severe, persistent (>3 days), or associated with fever or bloody stools. Although concerns exist regarding the potential for development of arthropathy and antimicrobial resistance with fluoroquinolone use in children, the US Food and Drug Administration has approved ciprofloxacin for anthrax and as a second-line agent for the treatment of urinary tract infections in children from 1 through 17 years of age.[82] Therefore, fluoroquinolones could be considered safe in children for the short course required for travelers' diarrhea. A 1- to 3-day course of ciprofloxacin at a dose of 30 mg/kg/day divided twice daily with a maximum dose of 500 mg twice daily is recommended for children with moderate to severe or bloody diarrhea.[67]

Rifaximin (Xifaxan), a nonabsorbed rifamycin derivative, has been approved in the US for treatment and prevention of travelers' diarrhea for people ≥12 years of age.[83] A liquid preparation is available in some countries for pediatric use. The drug is indicated for the management of noninvasive diarrheas such as those seen in ETEC infection, cholera, or EAEC infection when fever and bloody diarrhea are absent.

If travelers' diarrhea does not respond to a course of antimicrobial therapy, medical attention should be sought to investigate other possible causes of the diarrhea. Postinfectious irritable bowel syndrome is well recognized in adults as well as in children.

Emerging Infectious Diseases

Several infectious agents, such as Ebola virus, severe acute respiratory syndrome (SARS) and Middle Eastern respiratory syndrome (MERS) coronaviruses, chikungunya virus, Zika virus, the H5N1 strain of avian influenza virus, and the pandemic (H1N1) 2009 influenza virus have emerged as potentially widespread health threats. Given the constantly changing epidemiology of infectious diseases, pediatricians who advise families regarding travel health must keep informed of the current status of emerging infectious diseases that can pose a threat to the traveler. Several websites provide up-to-date information regarding such infections, including those of the WHO and the CDC (see Box 8.1).

Immunocompromised Travelers

Children with immunodeficiencies require special consideration at their pretravel evaluation because of increased risk of travel-related illness.[84] Most patients with an altered immune system, particularly people with decreased T-lymphocyte immunity, should not receive live vaccines because of risk of developing clinical illness from the vaccine strain.[84] IPV should be given instead of OPV to all members in the family of an immunocompromised person, and Vi typhoid vaccine should be administered instead of the Ty21a vaccine to an immunocompromised child, although the patient is not at risk if family members receive the live oral vaccine.[16,85] However, MMR, varicella, and yellow fever vaccines should be considered for human immunodeficiency virus (HIV)–seropositive children who are not severely immunocompromised (see Chapters 205 and 227). Killed or subunit vaccines can be administered to children with altered immunity, although responses to the vaccines can be diminished.[85] Asplenic patients may respond poorly to polysaccharide vaccines in particular. Patients with certain B-lymphocyte deficiencies, such as X-linked agammaglobulinemia and common variable immunodeficiency, should avoid OPV, vaccinia, and live bacterial vaccines, although other patients with humoral immunodeficiencies, including selective immunoglobulin (Ig) A and IgG subclass deficiency, must avoid only OPV; other live vaccines can be considered.

Some travel-associated illnesses can be more severe in immunocompromised travelers. Asplenic travelers are at greater risk of severe babesiosis and malaria, and organ and stem cell transplant recipients are more likely to develop bacteremia associated with gastroenteritis from *Salmonella* or *Campylobacter* spp.[86] HIV-seropositive travelers with low $CD4^+$ lymphocyte counts must be particularly conscious of risk factors associated with opportunistic infections such as *Toxoplasma gondii, Cystoisospora* (previously *Isospora*) *belli, Salmonella* spp., and *C. parvum,*[86] and therefore they must be particularly cautious regarding food, water, and animal exposures. In addition, because of the risk of disseminated strongyloidiasis in immunocompromised hosts, closed footwear should be encouraged strongly in such travelers.

Return From Travel

Routine posttravel screening generally is not required for asymptomatic, short-term travelers, although screening can be considered for long-term travelers, expatriates, adventure travelers, and people who have experienced significant illness while traveling.[4] If posttravel screening is indicated, the tests required should be determined by the potential exposures associated with the travel itinerary and any symptoms, if present.

Children who develop fever after travel should seek immediate medical attention, and parents must inform physicians caring for them of their travel itinerary. This is particularly critical if the itinerary has included a malaria-endemic area given that chemoprophylaxis cannot prevent all cases of malaria. Because malaria can manifest with nonspecific symptoms in children, any symptoms of fever, rigors, headache, malaise, abdominal pain, vomiting, diarrhea, poor feeding, or cough following travel to an endemic country should be evaluated promptly by a physician.[52,87]

Travel-related illness has been shown to be highly dependent on itinerary. In a report of disease and relation to place of exposure among ill returned travelers, significant regional differences in proportionate morbidity were reported.[4] Typhoid fever was seen most frequently in travelers returning from South Asia. Malaria was the most frequent cause of febrile illness among travelers returning from sub-Saharan Africa, whereas dengue was a more frequent cause of fever in most other areas. Rickettsial infections, primarily tickborne spotted fever, occur more frequently than malaria or dengue among travelers returning from South Africa.[4]

Host Defenses Against Infectious Diseases

OUTLINE

9 Immunologic Development and Susceptibility to Infection
10 Fever and the Inflammatory Response

9

Immunologic Development and Susceptibility to Infection

Paul K. Sue, Michal Meir, Maite de la Morena

The human immune system has evolved to protect the individual person from infectious microbes. It does this by using a complex interactive network of cells, proteins, and organs. Experiments of nature in humans, such as those recognized as the inherited disorders of immune function,[1–3] have taught us that despite the apparent redundancy of the system, quantitative and qualitative defects in individual components or pathways, or both, result in abnormal function and susceptibility to particular infections.

This chapter provides a general overview of the development of innate and adaptive immune responses, addresses some immunologic developmental characteristics unique to the fetus and newborn, and addresses susceptibility to pathogens in general terms.

Innate Immune Response

The innate immune system represents the first line of host defense against infection and includes the following: (1) antimicrobial products and physical barriers such as skin and mucosal surfaces; (2) receptors for pathogens, including toll-like receptors (TLRs), C-type lectin receptors, nucleotide-binding oligomerization domain (NOD) proteins, leucine-rich repeat–containing receptors (NLRs), and retinoic acid–inducible gene I protein (RIG-I) helicase receptors, which recruit immune cells to sites of infection[4]; (3) phagocytic cells such as neutrophils and macrophages; (4) dendritic cells (DCs); (5) complement proteins; and (6) natural killer cells.

Antimicrobial Products, the Skin, and Mucosal Barriers

In mammals, epithelial cells are capable of secreting antimicrobial peptides such as defensins and cathelicidins. Defensins contribute to host defense by disrupting the cytoplasmic membranes of microbes and inducing DC and lymphocyte chemotaxis. The α-defensins are produced by neutrophils, monocytes, and Paneth cells of the gut, whereas β-defensins are produced by epithelial cells. Cathelicidins exhibit both antimicrobial and immunomodulatory activity in the setting of injury and infection, and they are expressed by epithelial and peripheral blood cells. The sole cathelicidin expressed in humans, hCap18/LL-37, stimulates angiogenesis; it also induces chemotaxis of neutrophils, monocytes, and lymphocytes and demonstrates neutralizing capability against lipopolysaccharide (LPS).[5–9]

The skin's tight junctions between epithelial cells, thickness, and dry environment offer a shield against microbes. Loss of skin integrity, as occurs with wounds, burns, and inflammation, allows pathogens to breach this barrier. Antimicrobial peptides decrease the susceptibility to infection when skin barriers are compromised. Psoriasis and atopic dermatitis (AD), which are inflammatory skin conditions associated with skin disruption, demonstrate the role of these molecules in modulating infection risk. Although infection rarely is associated with psoriasis, patients with AD commonly are infected with *Staphylococcus aureus*. Human β-defensin 2 (HBD2) and the cathelicidin LL-37 appear to be strongly expressed in psoriasis and not in eczematous skin. Interleukin-13 (IL-13), produced under atopic conditions, suppresses the induction of these antimicrobial peptides.[10,11]

Intrauterine expression of antimicrobial peptides provides a robust defense against potential pathogens during fetal development. The α-defensin human neutrophil peptide (HNP) is detected in the cervical mucus plug, and placental and fetal membranes express HBD1 to HBD3.[12,13] During the third trimester of pregnancy, the fetus becomes covered by the vernix caseosa that contains antimicrobial peptides including α-defensins, cathelicidin LL-37, and psoriasin, a calcium-binding protein upregulated in psoriasis. Vernix extracts have antibacterial activity against gram-negative bacteria and antifungal properties against *Candida albicans*, whereas amniotic fluid–derived proteins and peptides show only the former activity.[14] At the level of the mucosal-epithelial interface, the expression of IL-17 by Th17 cells and the synthesis of defensins by keratinocytes also prevent invasion by *Candida* spp. Experimental models of mucocutaneous candidiasis have shed light on the pathogenesis of *Candida* infections in patients with hyperimmunoglobulinemia E (hyper-IgE), the autoimmune polyendocrinopathy syndrome, in patients with ectodermal dysplasia (APECED), and in patients with defects in the caspase recruitment domain-9 (CARD-9) protein.[15–20]

The more common entry pathway for pathogens is through the mucosal barrier. Mucosal epithelial cells secrete mucus that contains antimicrobial peptides. Mucus coats pathogens, thus allowing antimicrobial peptides to exert their action, and provides a vehicle for particles and pathogens to be cleared by the action of cilia. Within the respiratory tract, cilia move the mucus toward the upper airways, where it is either expelled by cough mechanism or swallowed. Ineffective clearance, as seen in patients with immotile cilia syndrome or cystic fibrosis and after lung transplantation, favors pathogen colonization. Cathelicidin LL-37 promotes bacterial phagocytosis by macrophages and thereby contributes to pathogen clearance; evolving therapeutic approaches using novel antimicrobial peptides in the setting of decreased mucosal clearance show promise.[21,22]

Surfactant-associated proteins, specifically surfactant protein A (SP-A) and surfactant protein D (SP-D), contribute to innate immune responses in the lung. Produced by type II pneumocytes and nonciliated respiratory epithelial cells, SPs belong to the family of proteins called collectins. SP-A and SP-D can interact with microorganisms, modulate local inflammatory responses, modulate neutrophil responses in vitro, and participate in clearance of pollens and other complex organic antigens.[23] In patients with severe, treatment-resistant asthma, SP-D levels in bronchoalveolar lavage fluids decline, whereas serum concentrations increase.[24] Potentially in the near future, this defective innate immune response within the airways may benefit from administration of recombinant SP-D.[25] Lysozyme, lactoferrin, histatins, and phospholipase A2 in tears and saliva also are potent antibacterial enzymes.[26,27] The gastrointestinal tract is protected by digestive enzymes, bile salts, fatty acids, and lysolipids. Paneth cells in the human gut secrete α-defensins and influence the virulence of orally ingested bacteria. Thus children and adults with infections caused by *Shigella* or virulent *Salmonella* strains have demonstrably decreased synthesis of HBD1 and cathelicidin LL-37 by colonic enterocytes. HBD2 expression also is reduced in enterocytes of patients with Crohn disease, and gastric mucosa–derived β-defensins are decreased in *Helicobacter pylori* infections. In vitro, *H. pylori* is susceptible to HBD2.

Endogenous antimicrobial peptides also appear to play a role in the regulation of host commensal bacteria and in the composition of gut microbiota. Decreased α-defensin expression in knockout murine models is associated with changes in the gut microbiome, with fewer Bacteroidetes and more Firmicutes.[28]

Pathogen Receptors and Toll-Like Receptors

Pathogen-associated molecular patterns (PAMPs) represent pathogen-specific carbohydrates and lipoproteins or nucleic acids expressed as part of their life cycle (i.e., bacterial DNA as unmethylated repeats of dinucleotide CpG, double-stranded [ds] or single-stranded [ss] RNA). Host proteins capable of recognizing such specific microbial patterns are called pathogen recognition receptors (PRRs). An example is mannose-binding lectin (MBL), a circulating soluble protein that binds mannose or fucose, residues on microbes and facilitates phagocytosis. Macrophages carry a C-type lectin, called macrophage mannose receptor (MMR), which binds carbohydrate moieties found on the surface of bacteria and also recognizes viruses such as the human immunodeficiency virus (HIV) and fungi.[29,30]

Toll-like receptors are a type of PRR capable of linking the innate and adaptive immune systems (see Chapter 10). These proteins are present on many cells including airway and gut epithelial cells, antigen presenting cells (B lymphocytes, macrophages, DCs, monocytes), hematopoietic stem cells, mast cells, regulatory T lymphocytes (Tregs), natural killer (NK) cells, and endothelial cells.[31] A total of 10 different TLRs have been identified in humans: TLR1, TLR2, TLR4, TLR5, TLR6, and TLR10 are found on cell surfaces, whereas TLR3, TLR7, TLR8, and TLR9 are localized within the endosomes. TLR11 has been found only in mice, appears to be a specific receptor for *Toxoplasma gondii,* and contributes to control of encephalitis in these animals.[32] TLR2 is involved in responses to gram-positive bacteria (peptidoglycans and lipoproteins) and yeast.[33] TLR4 mediates the interaction of gram-negative bacteria by transducing signals derived from LPS. A mouse model for TLR4 mutations renders the animal resistant to endotoxin but highly susceptible to gram-negative infection.[34] All TLRs are capable of interacting with different ligands (see Table 10.1 in Chapter 10). Respiratory syncytial virus (RSV) F protein, LPS, and *Pseudomonas* exoenzyme S have been shown to interact with TLR4, whereas flagellin is recognized by TLR5.[35] TLR2 recognizes envelope proteins of herpes simplex virus (HSV), whereas TLR9 identifies CpG motifs within the viral genome.[36]

TLR recognition of microbial products triggers the activation of downstream signaling pathways where myeloid differentiation factor 88 (MyD88) and toll–IL-1 receptor domain containing adaptor-inducing interferonβ (IFNβ) (TRIF) lead to activation of NF-κB and subsequent transcription of proinflammatory cytokines: tumor necrosis factor-α (TNF-α), IL-1, and IL-6. MyD88 recruits the IL-1R–associated kinase (IRAK) family of proteins: IRAK1 and IRAK4. Humans and mice with deficiencies in IRAK4 or MyD88 demonstrate severe impairment of IL-1 and TLR downstream signaling and are susceptible to recurrent and severe bacterial infections.[37–39] TRIF signaling results in activation of IFN regulatory factor-3 (IRF-3) and induction of type 1 IFN genes such as IFNα and IFNβ,[40] thus enhancing viral clearance.

TLR polymorphism can be linked to diseases such as asthma[41] and atherosclerosis.[31] TLR-9 has been linked to hepatic injury following severe renal ischemia reperfusion,[42] and a deletion of the signaling domain of TLR5 has been found to increase susceptibility to Legionnaire disease.[43] Finally, toll signaling pathways have been implicated in the pathogenesis of sepsis and shock.[44–46] Defects in TLR3 have identified inherited susceptibility to HSV encephalitis.[47–51] The stage of human development in which toll receptors appear is not clearly established. However, evidence indicates that TLR2 is developmentally expressed during fetal life from the early pseudoglandular to canalicular stages of human lung development[52] (see Chapter 11).

Phagocytes

The major phagocytic cells are neutrophils and macrophages. In humans, myeloid precursors are found in the yolk sac by day 19 of development, 2 days before the onset of blood circulation. Hematopoiesis then shifts to the fetal liver and finally to the bone marrow. In the bone marrow phagocyte development is under the control of multiple growth factors, including IL-3, granulocyte-macrophage colony-stimulating factor (GM-CSF), granulocyte colony-stimulating factor (G-CSF), and macrophage colony-stimulating factor (M-CSF). The marrow pool of neutrophils in adults is 20 times the number of neutrophils in circulation. The mechanisms responsible for the release of neutrophils from the marrow are complex. In familial neutropenias associated with maturational arrest, genes such as *HAX-1*,*CSF3R*, *ELANE*, and *WAS* have been identified as essential for neutrophil development.[53–57] The release or retention of neutrophils within the marrow compartment also is regulated by the interaction of signaling proteins on the cell surface, called chemokines, which interact with their ligands on bone marrow stromal cells. An example is the CXCR4/CXCL12 pair that permits retention of neutrophils in the marrow.[58,59] Mutations in CXCR4 lead to a rare condition called WHIM syndrome, for warts, hypogammaglobulinemia, immunodeficiency and myelokathexis. Myelokathexis indicates that neutrophils are retained in the marrow compartment, unable to be released, causing peripheral neutropenia. Once in the circulation neutrophils circulate for a few hours and then move into the tissues where they are active for 2 to 6 days.

At term, the neonatal peripheral neutrophil count is higher than that of adults, but reserved capacity to respond with an outpouring of phagocytic cells, which often are immature, appears to be minimal during infection. Newborn infants with septicemia often have severe neutropenia and depletion of phagocytic storage pools, a finding associated with high mortality rates.[60] The cause of this rapid depletion remains unknown, but the condition is likely exacerbated by the relative paucity of progenitor reserves in newborns' marrow. It is possible that decreased numbers of neutrophils at the site of infection contribute to the susceptibility of neonates to pneumonia and skin infection and to the development of multiple sites of infection after bacteremia or fungemia.[61] Lack of adequate numbers of cells at the site of infection can cause or result in functional deficiencies.

Monocytes also move from the circulation to tissue spaces, where they develop into macrophages, live for 2 to 3 months, and assume specialized characteristics generally determined by their location (e.g., lung, liver, or spleen). Circulating monocytes also have chemotactic and phagocytic activities and have receptors for immunoglobulin G (IgG) Fc domains (FcR), complement, and TLRs 2 to 9 along with CD14, an important molecule that mediates TLR4 activation by LPS.[62,63]

The function of phagocytes, which are particularly important in defense against bacteria and fungi, requires not only sufficient numbers of cells but also adequate ability to sense and migrate toward the site of infection (chemotaxis) and to ingest and kill microorganisms (phagocytosis). These processes are mediated by the expression of adhesion molecules, opsonins (complement and antibodies), and chemoattractants, IL-8 is the most important chemokine that attract neutrophils. At the site of infection, neutrophils engulf microbes and particulate matter by the mechanism of phagocytosis and kill the pathogen. Additionally, neutrophils secrete chemokines, release NETS (neutrophil extracellular traps), and die by apoptosis once their mission is accomplished. Macrophages subsequently clear any cellular debris. Monogenic defects at different stages of this process define unique syndromes (Fig. 9.1).

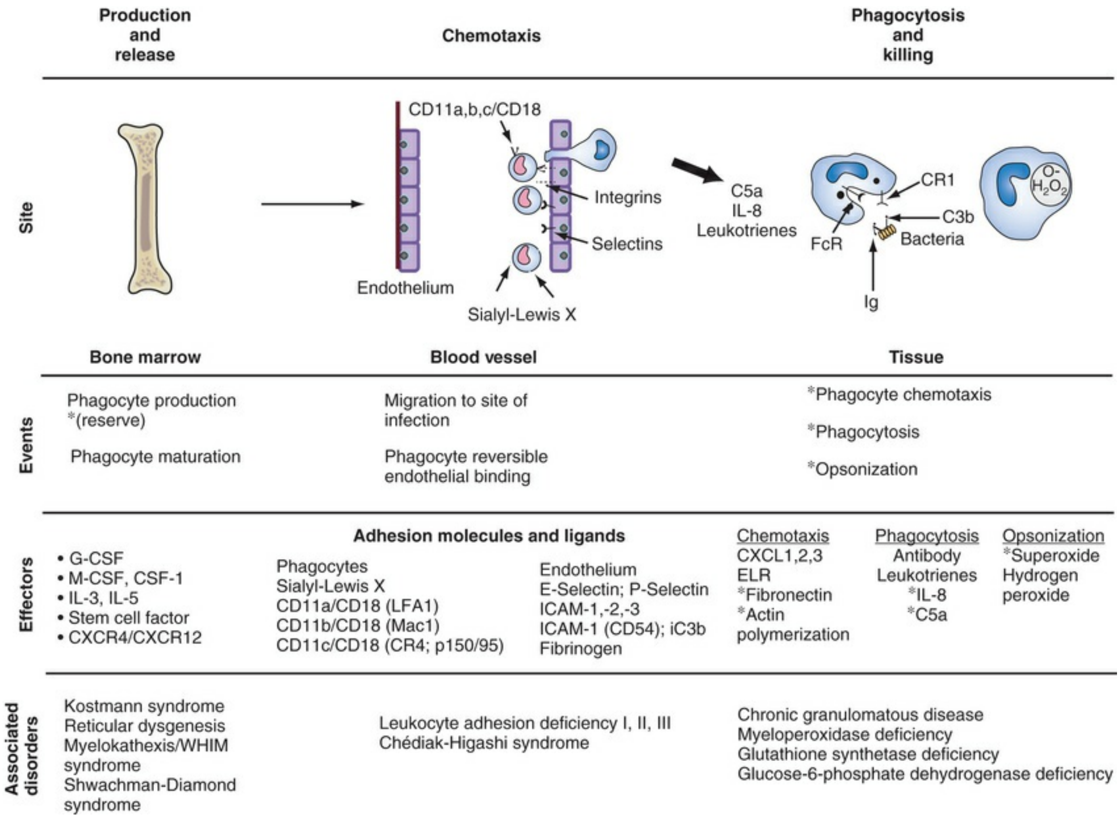

FIGURE 9.1 **Aspects of immunologic function. The *asterisks* indicate aspects that are immature or defective in the neonatal period. C, complement; CD, cluster of differentiation; CR, complement receptor; CXCL, CXC chemokine ligand; FcR, Fc receptor; G-CSF, granulocyte colony-stimulating factor; ICAM, intercellular adhesion molecule; Ig, immunoglobulin, IL, interleukin; M-CSF, macrophage colony-stimulating factor; WHIM, warts, hypogammaglobulinemia, immunodeficiency, and myelokathexis.**

Chemotaxis is the process by which phagocytes reach the site of infection. As a result of a local inflammatory response, endothelial cells within local vessels express adhesion molecules called selectins (CD62E, CD62P). These molecules reversibly bind to ligands on neutrophils (sialyl-Lewis X and PSGL1) and consequently make the neutrophil slow down and “roll” along the endothelium. Subsequently, another group of adhesion molecules, called integrins, is upregulated on the surface of neutrophils. Integrins are composed of one of three different α chains: CD11a, CD11b (CR3), or CD11c (CR4); they are noncovalently linked to a β chain, CD18, thus forming a CD11a/CD18 or LFX1, CD11b/CD18 or MAC-1, and CD11c/CD18 or p150,95 integrin complex. Integrin molecules “stop” the neutrophil, which then undergoes skeletal changes and migrates through the vascular lumen into the extravascular space by adhering to intracellular adhesion molecules (ICAMs). The sialic constituent of the group B *Streptococcus* (GBS) capsular polysaccharide mimics the human Lewis X antigen, thus making this a poor immunogen, and perhaps renders the neonate especially susceptible to this organism.[64] Defects in the expression of adhesion molecules have been described in humans: leukocyte adhesion defect (LAD) types 1, 2, and 3. Lack of integrin expression causes LAD-1, lack of sialyl-Lewis X expression causes LAD-2, and defects of integrin activation cause LAD-3. Patients have persistent leukocytosis, delayed separation of the umbilical cord, skin ulcers, periodontitis, and delayed wound healing.[65–67] L-selectin (CD62L) levels on fetal and immature infant neutrophils are comparable to those of adults. However, L-selectin expression is downregulated in the term neonate and is further diminished during acute bacterial infection in vivo.[68] Other defects in chemotaxis have been described.[65,69–72] In the newborn, defects in chemotaxis have been linked to decreased expression of Rac2, a signaling molecule, on umbilical cord blood neutrophils.[61]

Phagocytosis is an active process by which a previously bound pathogen is engulfed by a phagocyte in a membrane-bound vesicle called a phagosome. Both macrophages and neutrophils contain lysosomes, which are membrane-bound acidic organelles containing proteolytic enzymes and are capable of producing toxic products: nitric oxide (NO), superoxide anion (O_2^-), and hydrogen peroxide (H_2O_2). Fusion of the lysosome and phagosome membranes is necessary to kill the organism. Within azurophilic granules, a bactericidal/permeability-increasing protein (BPI) binds to bacterial LPS and kills gram-negative bacteria. BPI has been implicated in both neonatal sepsis[73,74] and chronic *Pseudomonas* infection in patients with cystic fibrosis.[75]

Production of O_2^- and H_2O_2 depends on the reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase enzyme complex (see Chapter 104). Defects in the different components of this enzyme complex result in the immunodeficiency known as chronic granulomatous disease. Affected patients are susceptible to infections with catalase-producing organisms, *Aspergillus* and *Nocardia* species. Because phagocytes are unable to kill the microbes, the host tries to contain the infection by calling in more macrophages and lymphocytes, with resulting granuloma formation. Once bacteria are killed, neutrophils die, whereas macrophages can generate new lysosomes. Patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency and glutathione synthetase deficiency also have neutrophil dysfunction and can have clinical features similar to those of chronic granulomatous disease.[76,77]

No well-described phagocytic defects have been reported in the developing human embryo. The capability of the newborn for nonopsonic adherence to organisms and phagocytosis is nearly equal to that of adult cells. However, deficiencies in chemotaxis and O_2^- production have been described.[64,78–81] Bacterial killing of umbilical cord blood phagocytes is effective against *Escherichia coli* and *Streptococcus pyogenes* and is similar to bacterial killing of phagocytes in adults, but it appears abrogated against GBS.[82] Abnormalities in chemoattractants (IL-8, complement fragment C5a, fibronectin)[83,84] and defective expression of complement receptors, such as C5a receptor, caused by C5a-mediated exocytosis of myeloperoxidase[85] also have been described. Defects in membrane fluidity and cytoskeletal changes can contribute to neutrophil motility defects as well.[86]

Dendritic Cells

DCs are the prototypic antigen-presenting cell. In humans, $CD34^+$ hematopoietic stem cells (HSCs) capable of generating DCs are detected in the fetal liver at 20 weeks of gestation, after which they are found mainly in the bone marrow. After birth, 1% to 3% of umbilical cord blood cells express CD34. During differentiation, these $CD34^+$ cells lose CD34 expression and express CD4, CD45RA, IL-3R, and major histocompatibility complex (MHC) class II antigens.[87,88] A class of DCs called Langerhans cells (LCs) was first described in 1868. It is difficult to identify the lineage ontogeny of human DCs. Bone marrow differentiation studies of DCs suggest a dual origin of DCs: myeloid and lymphoid.[89,90] LCs can derive from blood DCs.[91] Although lineage-specific markers are still being defined, transcription factors have been shown to regulate DC development. For example, transcription factor PU.1 is important for myeloid-derived DCs,[92] RelB is associated with DC activation,[93] and Ikaros proteins are transcriptional activators that influence chromatin remodeling and histone deacetylation.[94]

DCs are capable of regulating both innate and adaptive immune responses. With unique morphologic characteristics when activated, several pathogen receptors have been identified. Examples include TLRs that appear to be involved in DC maturation and scavenger receptors that mediate bacterial internalization, such as MAC-1 (CD11b/CD18) and the CR3 complex.[95,96] DCs induce antiviral cytotoxic T-lymphocyte responses producing IL-12 and IL-15, 2 cytokines critical for cytotoxic $CD8^+$ T-lymphocyte differentiation. Other DC subsets activate $CD4^+$ T lymphocytes through MHC II activation. Furthermore, activated DCs can promote B-lymphocyte proliferation into plasma cells by releasing soluble factors or by direct cell-cell interaction.[97]

In the skin, DCs are localized to the basal and suprabasal layers of the epidermis; in the murine gut, DCs are found in the Peyer patches; and in the human lungs they can be found within the airway epithelium, alveolar septa, visceral pleura, and vascular walls.[98–101]

While surveying the tissue environment, DCs can be recognized by an "immature" phenotype ($CD11b^{bright}$, $CD11c^{mo}$d, $CD86^{low}$, $ClassII^{low}$, $CD4^-$). On uptake of antigen or microbial products by different mechanisms of phagocytosis, DCs migrate through the afferent lymphatics to the regional lymph node, where they arrive as mature, nonphagocytic DCs ($CD40\ ^{high}$). These DCs can produce inflammatory cytokines and chemokines. Bacterial uptake of *Mycobacterium tuberculosis*, bacille Calmette-Guérin (BCG), *Saccharomyces cerevisiae*, *Corynebacterium parvum*, *S. aureus*, *Leishmania* spp., and *Borrelia burgdorferi* has been demonstrated in vitro.[102–105]

Complement

The complement system comprises a series of serum proteins that function in host defense as an enzymatic cascade (see Chapter 103). When microorganisms invade the host, activation of complement occurs locally by 1 of 3 pathways that converge at the stage of the formation of the enzyme C3 convertase. This enzyme cleaves complement component C3 into C3b and C3a. C3b, the major effector molecule of the complement system, binds to the bacterial cell membrane. This important molecule functions as an opsonin (to facilitate phagocytosis) and also helps cleave C5 into C5a and C5b.

C5a is a potent chemoattractant, and C5b is an integral part of the membrane-attack complex along with other terminal components: C6, C7, and C9. One pathway (classical) is activated by antibody-antigen complexes and thus depends on and enhances specific humoral immunity. A second pathway (alternative) can be activated by direct binding to the surface of some microorganisms and thus functions to provide innate (nonspecific) immunity. A third pathway (the MBL pathway) is initiated by the binding of MBL on mannose- and fucose-containing surfaces of bacteria and viruses, favoring their phagocytosis.

Until 18 months of age, the concentration of most complement proteins is lower than that in adults, with the exception of C7. Between 28 and 33 weeks of gestation, little development of the complement system appears to occur. Both the levels and function of the classical complement pathways are reduced in preterm neonates who are <34 weeks of gestational age, with C8 and C9 as the most markedly reduced at all gestational ages.[106] Deficiencies of complement activation in both classical and alternative pathways have been described.[107,108] Low levels of total hemolytic complement activity are significant predictors of death in neonates with septicemia.[108]

The molecular basis for defects in complement function in neonates and the details of the consequences are only partially understood. For example, a possible defect has been described in formation of a reactive thioester bond on C3 that is essential for opsonic and covalent binding of C3b to bacteria.[109] Inefficient killing of *E. coli* by neonatal sera appears to correlate with low concentrations of C9,[110] and it can be overcome by adding C9 to ampicillin-treated serum from neonates in vitro.[111] Deficient formation of C5a also can increase the neonate's risk of infection. Although levels of C5 are similar in adult and neonatal sera, neonatal sera form significantly less C5a on exposure to GBS type III.[112] This deficiency was apparent in newborn sera with antibody levels similar to those of adults and could be corrected by in vitro addition of C3. Finally, circulating serum MBL concentrations also can play a role in complement activity, with decreased serum concentrations associated with increased risk for neonatal sepsis.[113]

Hemolytic uremic syndrome occurs in childhood and frequently is preceded by a diarrheal illness caused by *E. coli* O157:H7. Plasma protein factor H and plasma serine protease I, regulatory proteins of the alternative complement pathway, have been associated with the nondiarrheal form of hemolytic uremic syndrome.[114,115] A study of 120 patients with nondiarrheal hemolytic uremic syndrome found that 10% of patients had mutations in the membrane cofactor protein (MCP; CD46). The onset typically was in early childhood, and most patients did not develop end-stage renal failure.[116]

Natural Killer Cells

NK cells form a subgroup of lymphocytes that exhibit cytolytic activity against tumor cells or cells infected with viruses (Table 9.1). In humans, NK cells are similar to cytotoxic $CD8^+$ T lymphocytes in their effector function, but they lack the T-lymphocyte receptor–CD3 complex and express the low-affinity Fc receptor for IgG (CD16, FcγRIII). NK cells comprise up to 10% of peripheral blood lymphocytes (PBLs) in adults.

TABLE 9.1

Comparison of Natural Killer Cells and Cytotoxic T Lymphocytes

Characteristic	Natural Killer Cell	Cytotoxic T Lymphocyte
Identification of target for kill	Nonspecific killing of virus-infected cells *or* Binding to antibody-coated cells by CD16 (ADCC)	TCR specifically identifies viral peptide within MHC class I molecule on surface of infected cell
Surface markers	CD16 and/or CD56	CD3/CD8
Signal(s) for activation	IFNα, IFNβ, IL-12	IL-2 and antigen (on surface of antigen-presenting cell)
Onset of function	1–6 days after infection	5–10 days after infection
Mechanism of killing	Granule exocytosis and secretion of toxin	Granule exocytosis and secretion of toxin

ADCC, antibody-dependent cell-mediated cytotoxicity; IFN, interferon; IL, interleukin; MHC, major histocompatibility complex; TCR, T-cell receptor.

NK cells appear in substantial numbers by 6 to 9 weeks of gestation in the embryonic liver and later in the fetal liver, thymus, and spleen. After birth, NK cells develop primarily from HSCs in the marrow and are driven to maturity by cytokines, in particular IL-15. IL-15 has the same intracellular signaling molecule, the common γ chain (γC), as other cytokines (IL-2, IL-4, IL-7, IL9, and IL-21). Mutations in γC are responsible for the X-linked form of severe combined immunodeficiency (SCID) that lacks both T and NK cells ($T^-NK^-B^+$ SCID).

Unlike cytotoxic T lymphocytes (CTLs), NK cells do not require MHC class I antigens to recognize their targets, do not recognize particular viral antigens, and can be activated by cytokines without previous exposure to the antigen, thereby making this cell an important contributor to innate responses.[117] However, NK cells can function with some degree of antigenic specificity because they can lyze cells that have been previously coated with specific antibody molecules. This process is called antibody-dependent cell-mediated cytotoxicity (ADCC). Both NK cells and CTLs mediate cytolysis in a similar manner because these 2 cell populations contain lytic granules composed of cytolytic proteins (perforin) and enzymes (granzymes). Perforin polymerizes when in contact with the target cell plasma membrane, thus creating pores; granzyme introduced through these pores induces target cell apoptosis.[118] Defects in the lytic granule content, priming, docking, and membrane fusion have been described in patients with hemophagocytic lymphohistiocytosis syndromes (see Chapter 12). In addition, defects in NK cell number or function have been recognized in many different human congenital deficiencies of immune function.[119]

NK cell activity in umbilical cord blood from infants born between 32 and 36 weeks of gestation is low compared with activity in infants born after 36 weeks. Antenatal glucocorticoid therapy for preterm labor can accelerate maturation of NK cells.[120] Compared with adult NK cells, neonatal NK cells have decreased cytotoxic activity and diminished ADCC until at least 6 months of age.[121] Conversely, when interferons (IFNs), IL-2, IL-12, and IL-15 are added to cultured neonatal NK cells, they can respond like adult cells.[122]

Neonatal HSV infection and severe recurrent herpesvirus infections in adults along with discoveries of genetic defects that cause NK deficiency provide evidence of the importance of NK cells in host defense.[119]

Adaptive Immune Response

The adaptive immune response is essential for host defense, as demonstrated by the increasingly recognized congenital deficiency syndromes. Specificity and immunologic memory are the most important consequences of adaptive immunity. Specificity is determined by the vast range of molecular diversity of antigen receptors. Immunologic memory is the ability to respond rapidly and effectively to pathogens previously encountered. The effector cells of the adaptive immune response are T and B lymphocytes, which develop from bone marrow–derived HSCs (Fig. 9.2). Lymphopoiesis is a tightly regulated sequence of events that leads to the expression of a functional antigen receptor on the surface of the lymphocyte. For B lymphocytes, it is the B-cell receptor (BCR) that represents surface immunoglobulin molecule, and for T lymphocytes, it is the T-cell receptor (TCR) complex. Cellular microenvironment, transcription factors, and posttranscriptional regulators such as microRNAs, cytokines, and chemokines, along with silencing or activation of certain genes at different stages of lineage commitment, are some of the multiple factors contributing to a successful and mature lymphocyte.[123,124]

B Lymphocytes

B lymphocytes play a critical role in pathogen-specific immunity by producing antibodies. B lymphocytes recognize soluble antigens through immunoglobulins anchored on their surface and differentiate into antibody-producing cells, called plasma cells, capable of secreting immunoglobulins. These proteins function alone (neutralization) or with complement or phagocytes to inactivate microorganisms.

The B-lymphocyte system is fully developed at birth. The origin of the human B lymphocyte is not well defined, but fetal B lymphocytes can be recognized in the yolk sac, omentum, and fetal liver. After birth, B-lymphocyte development takes place in the bone marrow. The ordered steps of B-lymphocyte development are marked by rearrangement of the immunoglobulin genes (see Fig. 9.2). Recombinase-activating genes *RAG1* and *RAG2*, transcription factors, and signaling molecules are required for normal B-lymphocyte development. Defects in B-lymphocyte development result in the classic X-linked Bruton agammaglobulinemia secondary to mutations in Bruton tyrosine kinase (BTK) or autosomal recessive forms of agammaglobulinemia.[125] A mature B lymphocyte can be identified by cell surface molecules: CD19, CD20, CD21 (the Epstein-Barr virus receptor) and CD40 (ligand for CD154, also called CD40LG, which is defective in hyper-IgM syndrome) among others. All these B-lymphocyte surface molecules are lost when the cell reaches the mature plasma cell state. Thus the monoclonal antibody anti-CD20, used for management of B-lymphocyte CD20$^+$ lymphomas and autoimmune conditions, does not deplete the plasma cell pool.

Flow cytometry analysis of circulating B lymphocytes has long allowed the identification of unique functional subsets within the B-lymphocyte compartment. A unique subset, known as B1 cells, plays a critical role in neonatal immunity. Although restricted in their repertoire, these B lymphocytes serve as the primary source of T-lymphocyte–independent antibody production and in experimental models, important in *Streptococcus pneumoniae* control.[126] Class-switched memory B lymphocytes, defined by the expression of cell surface markers CD27$^+$IgM$^-$IgD$^-$, have allowed for classification of patients with the primary immunodeficiency called common variable immunodeficiency (CVID), thereby providing insights into the pathogenesis of this heterogeneous disorder.[127]

Finally, regulatory B (Breg) lymphocytes are critical for controlling the inflammatory response by releasing anti-inflammatory mediators including IL-10.[128]

Passively Acquired Antibodies.

Neonates have a limited serum antibody repertoire (at least 10^{11}) of actively formed, self-produced antibodies because they have not had the opportunity to encounter pathogens. This limitation is alleviated by transplacental transfer of maternal antibody, which occurs by a selective, active process, starting at approximately 20 weeks of gestation but more consistently after 35 weeks of gestation. Only IgG transport occurs and is mediated by the neonatal Fc receptor (FcRn). At birth, term infants have serum IgG levels that are equal to or exceed maternal levels by 5% to 10%. Because most antibody transfer occurs during the third trimester of pregnancy, preterm infants can have very low levels. For example, most infants born at 32 weeks of gestation or earlier have serum IgG levels lower than 400 mg/dL. Transplacentally acquired antibody disappears rapidly after birth and reaches a nadir at 3 months (Table 9.2). However, these low levels of maternal IgG antibody at 3 months of age appear to be associated with less risk of infection than would be expected. A longitudinal study of the ability of preterm infants to form specific antibodies provides a partial explanation for this low risk. By approximately 9 months of age, infants have formed specific IgG antibodies in response to immunizations, and their antibodies have functional opsonic activity against *E. coli* and coagulase-negative staphylococci.[129–132]

TABLE 9.2

Concentration of Serum Immunoglobulin G in Term and Premature Infants

Postnatal Age	Gestational Age: Mean Serum IgG (mg/dL)		
	25–28 wk[a]	**29–32 wk**[a]	**Term**[b]
1 wk	251	368	1,031
3 months	60	104	430
6 months	159	179	427

[b] Data for term infants based on umbilical cord blood and samples at 1 to 3 months

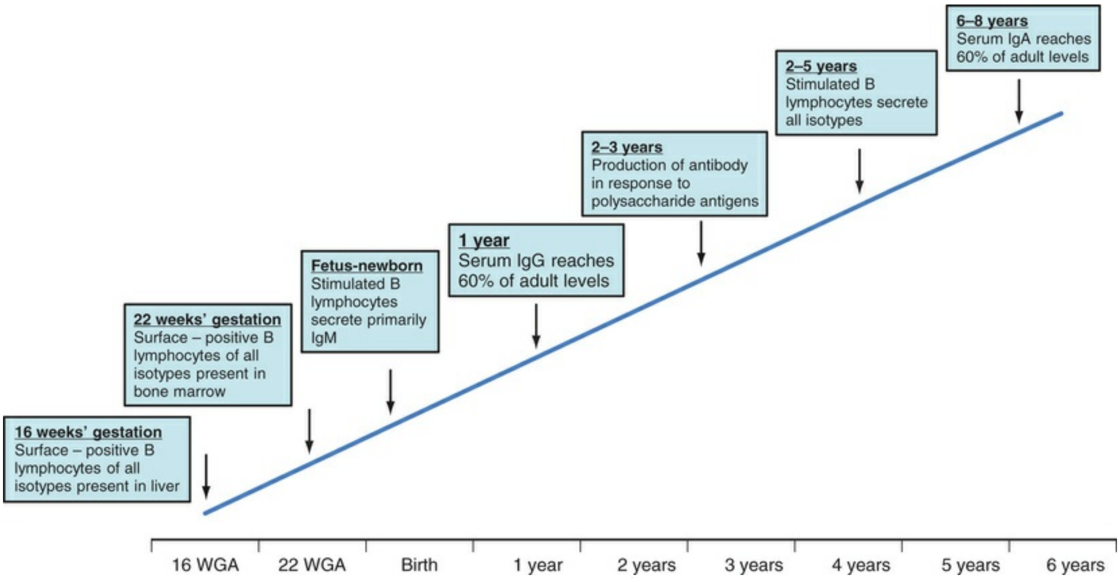
and 4 to 6 months of age.[148]

IgG, immunoglobulin G.

The maternal repertoire of specific antibodies is critical for protection of the newborn infant from commonly encountered pathogens. In a landmark report, Baker and Kasper[133] demonstrated that a concentration of ≤2 μg/mL of serum antibody to GBS type III in umbilical cord blood correlated with susceptibility to invasive disease. Evidence of the protective effect of maternal antibodies against herpesviruses such as HSV and varicella-zoster virus is well established.[134] Many gram-negative organisms require IgM antibodies and complement for efficient opsonization. Because IgM does not cross the placenta, neonatal sera opsonize these organisms poorly. The apparent protective role of transplacental IgG antibodies has led to extensive attempts to prevent or treat neonatal sepsis with passively administered antibodies. In a randomized treatment trial involving 3493 neonates, no effect of IgG therapy on mortality rates or major disability at age 2 years was observed.[135] This trial and previous studies underscore complex mechanisms necessary for the newborn to clear pathogens

Active Production of Antibodies.

The ability of newborn infants to produce an active antibody response to antigenic stimulation develops in an orderly fashion. An adult pattern of antibody responses is not acquired until 4 to 5 years of age. Analysis of the factors responsible for this developmental pattern is complex because production of antibody depends not only on B-lymphocyte maturity but also on interactions with other cells that mature at different rates (Fig. 9.3). After birth, active production of IgG slowly increases, with IgG being the last isotype to achieve adult concentrations. Postmortem studies of fetuses suggest that secretory IgA (sIgA)–containing epithelial cells appear at 20 to 21 weeks of gestation, and their number increases from 2.5 cells/10,000 μm at 23 to 26 weeks to 8 cells/10,000 μm at 36 to 40 weeks. In fetuses with pneumonia or sepsis, sIgA-containing epithelial cells in the trachea, bronchi, and intrahepatic duct decrease and, at times, completely disappear. This finding suggests that sIgA is an important component of mucosal immunity as early as 20 weeks of gestation.[136,137]



6–8 years
Serum IgA reaches 60% of adult levels
2–5 years
Stimulated B lymphocytes secrete all isotypes
2–3 years
Production of antibody in response to polysaccharide antigens
1 year
Serum IgG reaches 60% of adult levels
Fetus-newborn
Stimulated B lymphocytes secrete primarily IgM
22 weeks' gestation
Surface – positive B lymphocytes of all isotypes present in bone marrow
16 weeks' gestation
Surface – positive B lymphocytes of all isotypes present in liver

6 years

FIGURE 9.3 **Developmental milestones of humoral immunity. Ig, immunoglobulin; WGA, weeks' gestational age.**

Fetuses can produce IgM antibodies, predominantly in response to intrauterine infection. Preterm infants respond nearly as well as term infants to immunization beginning at 2 months with diphtheria and tetanus toxoids and pertussis (DTP), diphtheria and tetanus toxoids and acellular pertussis (DTaP), poliovirus, and hepatitis B vaccines. Term infants immunized or infected during the first few days of life usually produce protective antibody responses, although at somewhat lower levels than adults.

The presence of fetal bone marrow B-lymphocyte pools similar in size to those of adults and with comparable isotype diversity suggests that B-lymphocyte functional deficits may reflect a developing memory repertoire with increased specificity to antigen or the need to generate T lymphocytes capable of producing strong B-lymphocyte signals, rather than inherent B-lymphocyte immaturity as a sole factor. Studies of B-lymphocyte activation have revealed much about the complexities of B-lymphocyte signaling and suggest possible mechanisms for deficits of B-lymphocyte function that can be examined in healthy neonates.

In contrast to the early development of antibody responses to most protein antigens, responses to thymus (T)–independent antigens, such as polysaccharides, develop later. The basis for this process remains unclear. Umbilical cord blood B lymphocytes are capable of activation in vitro with T-independent activators. This finding suggests that signal transduction pathways within the B lymphocyte are normal. However, the mechanism of B-lymphocyte activation by polysaccharides differs from protein antigens in that it involves co-stimulation through a B-lymphocyte surface molecule called CD21 and can be influenced by the expression of yet another B-lymphocyte surface molecule: CD22. Both CD21 and CD22 were noted to be reduced on stimulation of neonatal B lymphocytes, thus suggesting a unique role for these molecules in antibody production to polysaccharide antigens. However, normal functional antibody responses to Pneumovax (Merck, Whitehouse Station, NJ), a pure polysaccharide pneumococcal vaccine, has been reported in children as young at 12 months.[138,139]

Although the extent to which neonatal deficiencies of neutrophil function, complement, or antibody contribute to the increased risk of infection is unknown, these factors are important in vitro in the opsonophagocytic killing of *E. coli*, GBS, and *Candida* species. The combined effects of these deficiencies undoubtedly contribute to the increased risk of serious infection with these pathogens in neonates.[140]

T Lymphocytes

T lymphocytes play a central role in regulation of antigen-specific immune responses, by modulating the function of antigen-presenting cells, B lymphocytes, and other T lymphocytes, both through contact with (receptor binding) and secretion of cytokines and by direct killing of target cells. HSC progenitors migrate to the thymus where, similar to B lymphocytes, T lymphocytes rearrange their TCR genes by somatic recombination (see Fig. 9.2). In contrast to BCRs, TCRs do not diversify their variable (V) region genes through somatic hypermutation. Moreover, unlike B lymphocytes, T lymphocytes develop into 2 populations: αβ T lymphocytes (the most abundant, 95% of the circulating pool) or γδ T lymphocytes (approximately 5% to 10% of the circulating pool). Maturing T lymphocytes move within the thymus in a directed manner from the cortex to the medulla (see Fig. 9.2). The expression of surface molecules identifies their state of maturity. Thus T lymphocytes start as double-negative ($CD4^-/CD8^-$) stage → double-positive ($CD4^+/CD8^+$) → single-positive $CD4^+$ or $CD8^+$ just before being released into the periphery. During maturation in the thymus, T lymphocytes are selected to proceed to the next developmental stage in response to the interactions of a successfully assembled TCR with self-MHC–self-peptide complexes. As with B lymphocytes, *RAG1* and *RAG2* genes and their products are identified during early stages of development, and the expression of transcription factors and signaling events drive clonal commitment.[141]

Understanding normal human T-lymphocyte development in the thymus led to the identification of T-lymphocyte receptor excision circles (TRECs) as biomarkers for T-lymphocyte lymphopoiesis that defined naïve T lymphocytes coming out of the thymus.[142] Because TRECs can be quantitated by polymerase chain reaction, DNA isolated from dried blood spots collected for newborn screening provided an opportunity to identify infants born with absent or very low number of T lymphocytes as a result of SCID. In 2010 the US Department of Health and Human Services Secretary recommended that SCID be added to the newborn screening panel. It is now recognized that the prevalence of SCID in the United States is estimated to be 1 in 58,000 live births, and screening has permitted the initiation of lifesaving therapies for these infants before the onset of infections.[143]

Umbilical cord blood has an increased absolute number of naïve T lymphocytes, compared with the peripheral blood of older children and adults (Table 9.3). The mean peripheral T-lymphocyte counts in newborn infants, children, and adults vary with age and are highest in healthy infants. The ratio of $CD4^+$ to $CD8^+$ lymphocytes in umbilical cord blood is the same as that in adults (1.2), but it is increased to 1.9 from birth through 11 months of life.[144,145] Although the absolute number of circulating T lymphocytes decreases beyond the neonatal period, the percentage of T lymphocytes among the total lymphocyte population increases. Advances in flow cytometry have permitted the identification of different subsets of circulating T lymphocytes. Naïve $CD4^+$ T lymphocytes can differentiate into distinct subpopulations with a variety of different functions. The main functional classes are Th1, Th2, Th17, and Treg. In addition, T-follicular helper lymphocytes (T_{FH}) provide help to B lymphocytes in the lymphoid follicles.

TABLE 9.3

Comparison of Newborn and Adult T Lymphocytes

Characteristics	**Newborn**	**Adult**
Repertoire of TCR binding specificity	Unknown	Broad
Mean T-lymphocyte count	3100/mm^3	1400/mm^3
CD4$^+$/CD8$^+$ ratio	1.2	1.2
Proliferation (mitogen-stimulated)	Good	Good
Proliferation (antigen-stimulated)	Poor	Good
Ability to provide help to B lymphocytes	Poor	Good
CD45RA$^+$ (naïve CD4$^+$ T lymphocytes)	90%	48%
Production of cytokines	Decreased IFNγ, IL-4, G-CSF, GM-CSF, IL-3	Multiple

G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; IFN, interferon; IL, interleukin; TCR, T-cell receptor.

Most mature T lymphocytes (95%) recognize antigen through a TCR. Contrary to B lymphocytes, T lymphocytes can recognize only those antigens that are displayed on cell surfaces. These antigens can be derived from pathogens that replicate within the cell such as viruses or intracellular bacteria or products internalized from the extracellular space. T lymphocytes recognize intracellular pathogens because infected cells display on their surface fragments or peptides derived from the pathogens' proteins. The molecules responsible for holding these peptides within their groove are the MHC molecules. Two classes of MHC molecules are recognized: class I, which include human leukocyte antigen-A (HLA-A), HLA-B, and HLA-C; and class II: HLA-DR, HLA-DQ, and HLA-DP. MHC class I molecules are present on all nucleated cells, whereas MCH class II are present on antigen-presenting cells and other specialized cells. Peptide–MCH class I complexes (MHC I) present antigen to cytotoxic T lymphocytes (CD8$^+$), and peptide–MHC class II complexes (MHC II) present antigen to helper T lymphocytes (Th1/CD4$^+$).

Cytosolic peptides derived from vaccinia virus, influenza virus, rabies virus, and *Listeria* are coupled to MHC I molecules on the surface of the infected cell. These peptide–MHC I complexes then can be recognized by cytotoxic CD8$^+$ cells that kill the targeted infected cell. *Mycobacterium tuberculosis*, *Mycobacterium leprae*, *Leishmania donovani*, and *Pneumocystis jirovecii* are localized within macrophage vesicles, and their derived peptides are coupled to MHC II molecules on their surfaces. Peptide–MHC II complexes are recognized by CD4$^+$ (Th1) cells. These activated T lymphocytes then produce IFNγ, which recruits more macrophages; a granuloma is formed, and the activated macrophage kills its intracellular pathogen by releasing the antimicrobial products within its vesicles. *Clostridium tetani*, *S. aureus*, *S. pneumoniae*, polioviruses, *P. jirovecii*, and *Trichinella spiralis* require both humoral and cellular immune response for effective killing.[146,147] It is therefore understandable that defects in antigen processing, presentation, and both T-lymphocyte and B-lymphocyte effector functions make the individual person susceptible to pathogens that require a particular pathway for clearance.

Proliferative Responses.

Neonatal T lymphocytes proliferate normally in response to phytohemagglutinin (PHA) and allogeneic cell stimulation, but they have a limited ability to develop immunologic memory.[148–150] Umbilical cord blood cell populations have been shown to contain large numbers of naïve T lymphocytes (CD45RA$^+$) versus memory T lymphocytes (CD45RO$^+$).[151,152] This proportion declines slowly to 61% by 7 years of age as naïve lymphocytes are replaced by memory lymphocytes, a process that probably represents an intrinsic maturation of T lymphocytes as a consequence of antigenic stimulation.[153,154]

Cytokine Production.

The predominant naïve phenotype of newborn T lymphocytes may further account for differences in cytokine production. Neonatal T lymphocytes produce less INFγ, IL-2, IL-4, IL-10, and TNF-α than adult T lymphocytes in response to various stimuli. Modest reduction of GM-CSF and decreased G-CSF and IL-3 production and gene expression also are described.[154–158] Dysregulation of various immunoregulatory and cytokine genes in umbilical cord blood mononuclear cells could explain the apparent immaturity of neonatal cell-mediated immunity.[159]

T lymphocytes influence the functional activity of many other cell types. Decreased T-lymphocyte function in neonates is likely to increase susceptibility to infection by many pathogens. For example, decreased T-lymphocyte help for antibody production and isotype switching by CD40L-CD40 interaction,[160] along with decreased phagocytic function, probably contributes to increased susceptibility to bacterial infection. Susceptibility to viral infection and other intracellular pathogens, such as *T. gondii* and *Listeria*, probably results from decreased cytolytic activity of T lymphocytes and decreased IFNγ.[154] The specific role of T-lymphocyte immaturity in severe clinical HSV infection in neonates is suggested by the observation that neonates infected with HSV showed decreased antigen-specific cellular responses (decreased proliferation and IFNγ production) compared with adults who had primary HSV infection.[161]

Interrelationships and the Future

Humans resist infection in several ways. The innate defense mechanisms act first and may be capable of eliminating the pathogen completely. If not, adaptive responses are initiated and put in place by releasing clonally expanded effector T and B lymphocytes to the sites of infection. The mechanisms that regulate the final clearance depend on the pathogen itself. For certain pathogens, an effective adaptive immune response leads to a state of protective immunity. However, many pathogens evolve mechanisms that permit evasion from an effective immune response. Since Edward Jenner's studies of cowpox more than 200 years ago, vaccination has become a successful application of our interpretation of nature's experiments. Furthermore, the study of patients with primary immunodeficiency not only has provided a better understanding of biologic systems as they relate to humans but also has offered therapeutic options for this group of patients as well as for others. Only through the understanding of the basic intrinsic mechanisms that regulate immunity will further pathogenic mechanisms be elucidated and therapies developed.

Fever and the Inflammatory Response

Grant S. Schulert, Alexei A. Grom

Fever

Pathogenesis

Fever is defined as a centrally mediated rise of body temperature higher than the normal daily variation in response to a variety of pathologic insults.[1] The rise in body temperature is a regulated process triggered by the elevation of the thermoregulatory center set point, located in the hypothalamus, caused by pyrogenic substances. Various microbial products, including endotoxins and exotoxins, are exogenous pyrogens. Although these molecules can act directly to induce fever, evidence indicates that they stimulate host cells to secrete mediators known as endogenous pyrogens including cytokines produced during the inflammatory response, most notably tumor necrosis factor-α (TNF-α), interleukin-1 (IL-1), IL-6, and, to a lesser degree, the interferons (IFNs).[2–4] Fever is more likely to be caused by infection, but any inflammatory, neoplastic, immunologic, or traumatic event also can generate fever.

Once pyrogenic cytokines are produced, they enter the systemic circulation and stimulate the rich vascular network surrounding the preoptic area of the hypothalamus (thermoregulatory center). Here they activate phospholipase A_2, which liberates plasma membrane arachidonic acid as a substrate for the cyclooxygenase pathway.[5,6] Some cytokines can increase cyclooxygenase expression directly and cause liberation of the arachidonate metabolite prostaglandin (PG) E_2 (PGE_2). Because this small lipid molecule diffuses easily across the blood-brain barrier, some investigators believe PGE_2 to be the local mediator that activates thermoregulatory neurons, which in turn raise the thermostat set point (Fig. 10.1). Although the blood-brain barrier prevents migration of large proteins such as circulating cytokines, the presence of pyrogenic substances has been demonstrated at the circumventricular organs, which lack a blood-brain barrier.[6]

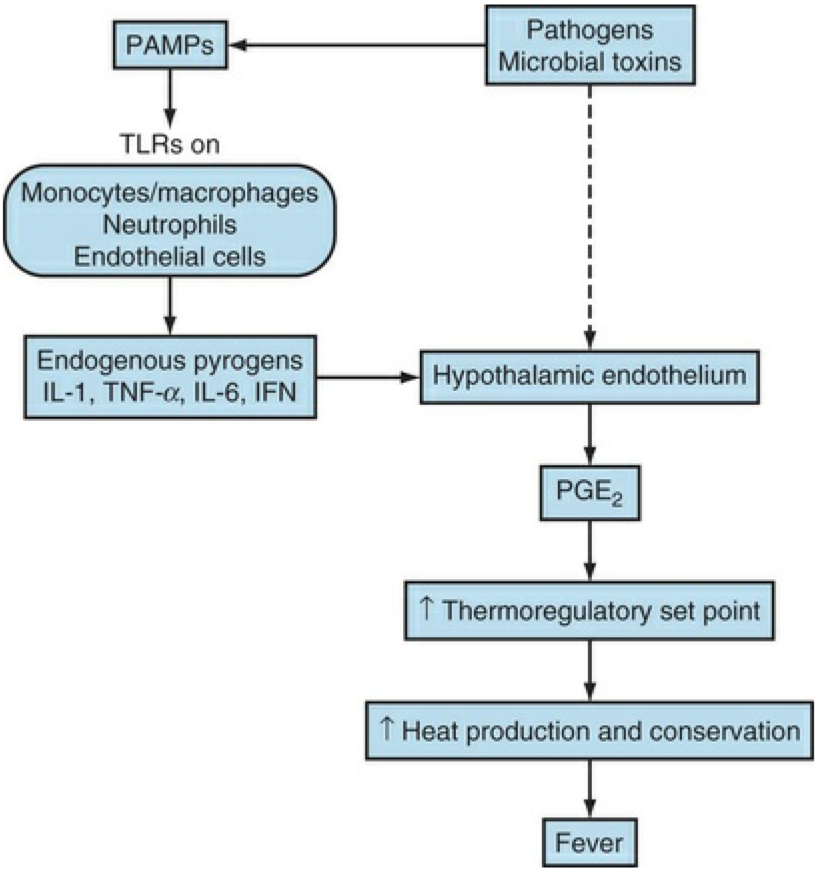

FIGURE 10.1 **Induction of fever: central and peripheral mechanisms. IFN, interferon; IL, interleukin; PAMPs, pathogen-associated molecular patterns; PGE_2, prostaglandin E_2; TLRs, toll-like receptors; TNF-α, tumor necrosis factor-α.**

As a result, activation of peripheral mechanisms that stimulate the sympathetic chain and terminal adrenergic efferent nerves leads to vasoconstriction (heat conservation) and muscle contraction (heat production), which generate fever. Autonomic (decreased sweating) and endocrine (decreased vasopressin secretion to reduce amount of body fluid to be heated) pathways contribute to thermoregulation.[6] Conservation and production of heat continue until the temperature of the blood bathing the hypothalamic neurons matches the new elevated setting. When cytokine stimulation ceases, the hypothalamic set point is reset downward, and the process of heat loss through vasodilation and sweating is initiated. In addition to these thermoregulatory mechanisms, certain areas in the cerebral cortex are stimulated to promote behavioral changes designed to help control temperature, such as the heat-saving behavior of desiring extra blankets during a shaking chill and the heat loss behavior of removing clothing.

Fever must be distinguished from hyperthermia, which is an uncontrolled increase in the body temperature. Hyperthermia typically develops when exogenous heat exposure or endogenous heat production exceeds the body's ability to lose heat. This condition occurs despite a normal hypothalamic set point.

Clinical Aspects

Body temperature varies with age, physical activity, and time of day; it fluctuates from less than 37°C in the early morning to up to 38°C in the late afternoon. Normal diurnal fluctuation also is exhibited in febrile patients. In general, values higher than 37.8°C are considered to be fever, although single elevations do not always imply a pathologic process. Very young infants tend to have blunted fever rises more often than older children in response to the same antigenic stimulus. In clinical practice, core temperature is measured best by a rectal thermometer; oral temperatures can be influenced by previous ingestion of hot or cold foods and are reduced in the presence of open-mouth breathing in patients with tachypnea. Axillary readings are less reliable and typically are 0.5°C lower than oral values and 1°C lower than rectal readings. In theory, the tympanic membrane is an ideal site for measuring core body temperature because the membrane is perfused by a tributary artery supplying the body's thermoregulatory center. Unfortunately, numerous studies using different instruments have shown that although convenient, tympanic membrane thermometers give highly variable readings compared with simultaneously obtained oral or rectal readings.[7,8]

Antipyretic Therapy

Substantial evidence suggests that fever is more beneficial than harmful for the host.[9] High temperatures interfere with the replication and virulence of certain pathogens and may speed the recovery of infected patients. In addition, some immunologic responses (e.g., leukocyte migration and phagocytosis, as well as IFN production) are enhanced by temperature elevation. Fever also induces stress responses in microbes, thus leading to increased production of pathogen-associated molecular patterns (PAMPs) that further enhance the immune response (see later).[10] Moreover, fever serves to attenuate immune responses by promoting caspase cleavage and accelerating leukocyte apoptosis.[11,12] As such, although short courses of standard antipyretic drugs carry a low risk of toxicity, and most have analgesic properties as well, these agents may prolong an illness or diminish a vaccine response. Nonspecific suppression of fever also may eliminate an important clue for the need for further diagnostic investigations or for changes in therapy

Because fever is generated after local hypothalamic stimulation by PGs, inhibitors of the cyclooxygenase enzyme system are potent antipyretics. Although acetaminophen is a poor cyclooxygenase inhibitor in peripheral tissue, acetaminophen is oxidized in the brain, and the resulting compound inhibits cyclooxygenase activity. Aspirin inhibits PG synthetase in a wide variety of tissues, and its antipyretic effect is equivalent to that of acetaminophen. Because these drugs are broad cyclooxygenase inhibitors, they have many side effects. The potential association between aspirin therapy in children with influenza or varicella and the development of Reye syndrome precludes the use of this drug in children with these conditions. Although several nonsteroidal anti-inflammatory drugs (NSAIDs; e.g., ibuprofen, naproxen) have antipyretic effects similar to those of aspirin and acetaminophen, NSAIDs are anti-inflammatory and are associated with more adverse effects than is acetaminophen. NSAID use for treatment of simple fever is ill advised and should be restricted for conditions requiring an anti-inflammatory agent.

Corticosteroids are among the most potent antipyretic drugs because they inhibit the activity of phospholipase A_2, thereby interfering with arachidonic acid metabolism and PG synthesis, and they also block the production of pyrogenic cytokines (i.e., TNF, IL-1, and IL-6) at a proximal step in the genesis of a febrile response. Similarly, IL-1 blockade, most notably with the recombinant IL-1 receptor antagonist anakinra, is highly efficacious for treating fever. However, these agents should not be used in management of simple fever or infectious episodes without specific indications (see Chapter 15).[13]

The use of a cooling blanket or water-alcohol bathing as an attempt to accelerate peripheral heat losses is uncomfortable, and water-alcohol bathing can lead to alcohol toxicity. Peripheral cooling, in the absence of pharmacologic downregulation of the hypothalamic set point can be counterproductive because cold receptors in the skin send signals to the spinal cord and brain that induce reactive vasoconstriction and shivering, thus increasing heat conservation and eliciting oxygen consumption and heat production.

Inflammatory Response

The body has a sentinel system that maintains immunologic surveillance to avoid pathogen-induced derangements of homeostasis. Once this background activity is circumvented, a host inflammatory response ensues. The *inflammatory response* is a complex reaction involving the migration of elements of the immune system into sites of tissue injury or microbial invasion.[14] In most clinical situations, the inflammatory response, with or without the aid of antimicrobial therapy, is effective in resolving the infection and contributes to tissue remodeling. If the infection is not brought under control, however, the infectious stimulus gains access to the circulation and stimulates the release of a cascade of systemic and local effector molecules. This host reaction, called the systemic inflammatory response syndrome, can be caused by a variety of immunologic, traumatic, surgical, or drug-induced insults; most often, however, an infectious agent is the trigger (see

Chapter 11). The sum of the balance of the microbial damage–host response framework can result in host damage caused by the microbe, the host, or both.

Overview of the Innate and Adaptive Immune Systems

The immune response to infection and cellular injury can be broadly divided into 2 categories: innate and adaptive immunity.[15] The initial immune response is mounted by the innate immune system, involving neutrophils, monocytes and macrophages, dendritic cells, and natural killer (NK) cells. These cells use pattern recognition receptors (PRR) to mount an immediate response associated with the production of IL-1, IL-6, and TNF-α. PRRs have broad specificity for highly conserved and often integral microbial structures called PAMPs, as well as endogenous ligands released as a result of tissue damage called damage-associated molecular patterns (DAMPs). In addition to inflammatory cytokines, many other pathways are activated, including synthesis of degradative enzymes and enzymes responsible for production of small molecule mediators of inflammation such as arachidonic acid derivatives (Fig. 10.2).

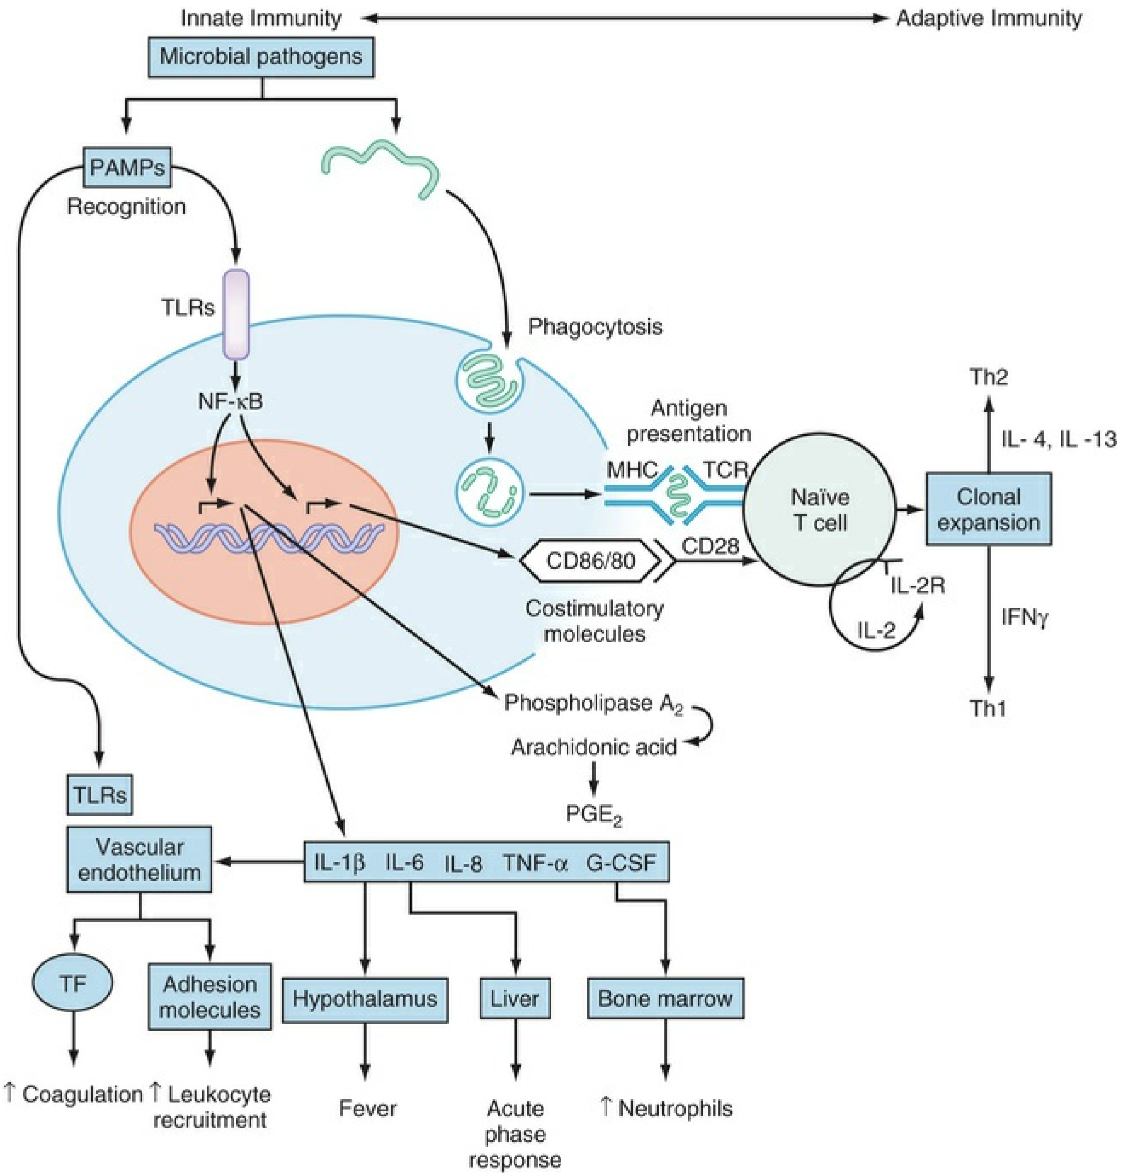

FIGURE 10.2 Induction of the innate and adaptive immune responses. The recognition of pathogen-associated molecular patterns (PAMPs) by toll-like receptors (TLRs) results in the activation of intracellular signaling pathways leading to the activation of the transcription factor nuclear factor-κB (NF-κB). The translocation of NF-κB into the nucleus leads to upregulation of expression of genes encoding proinflammatory cytokines interleukin-1 (IL-1), IL-6, tumor necrosis factor-α (TNF-α), and colony-stimulating factors (CSFs). It also leads to increased expression of costimulatory molecules involved in antigen presentation and induction of the adaptive immune responses. The cytokines IL-1, IL-6, TNF, and granulocyte CSF (G-CSF), through their effects on hypothalamus, bone marrow, liver, and vascular endothelial cells, initiate the inflammatory cascade. CD, cluster of differentiation; IFN, interferon; IL-2R; interleukin-2 receptor; MHC, major histocompatibility complex; PGE_2, prostaglandin E_2; TCR, T-cell receptor; TF, tissue factor; Th1 and Th2, helper T lymphocyte, subtypes 1 and 2.

The contribution of the adaptive immune system becomes important at later stages of the immune response. The adaptive immune response is mediated by T and B lymphocytes and is distinguished from innate immunity by high specificity and long-lasting memory. The adaptive immune response is influenced by the generation of helper T-lymphocyte subsets (Th) and the subsequent production of "effector" cytokines by these cells. Naïve T lymphocytes recognize antigen encountered by antigen-presenting cells (APCs), undergo activation and expansion, and can differentiate into 2 subsets determined by the cytokine milieu. The IFNs and IL-12 drive Th1 differentiation, and these cells secrete IFNγ and promote mainly cellular immunity. In contrast, IL-4 induces Th2 differentiation, leading to production of IL-4, IL-5, IL-10, and IL-13 and the promotion of humoral immunity.[16] Infection by intracellular pathogens induces primarily a Th1-dominated response that protects against the majority of microorganisms, whereas some parasitic infections induce a Th2 response that is associated with resistance to helminths.

In addition to instructive cytokines, APCs use several costimulatory molecules, including CD80 and CD86, to signal T lymphocytes and induce their clonal expansion. Antigen presentation in the absence of costimulatory molecules leads to cell anergy. Because the engagement of the innate receptors on APCs leads to upregulation of expression of the costimulatory molecules and enhances antigen presentation, the interaction between the innate and adaptive systems at this step becomes very important.[15]

Receptors of the Innate Immune System

The PRRs that initiate the innate immune response detect infectious agents by recognizing PAMPs, which are shared by large groups of microorganisms but are not present in mammalian cells.[15] Probably the best-known PAMPs are lipopolysaccharides (LPSs) from the outer membrane of gram-negative bacteria. LPS administration induces local and systemic inflammation and tissue damage similar to that observed in infection caused by gram-negative bacteria themselves. For this reason, the LPS-induced response has been used for several decades as a model of inflammation. In 1998, the principal component of the human LPS receptor was identified as toll-like receptor 4(TLR4). The term is based on structural similarities with the *Drosophila* protein "toll," which is required for the normal development of the flies and protection against the fungus *Aspergillus*.[17,18] At least 9 other human TLRs have been identified, each of which appears to recognize a distinct set of PAMPs (Table 10.1). It is becoming clear that, collectively, TLRs can detect most (if not all) microbes,[15,19–21] including protozoa, bacteria, viruses, and fungi. In addition, TLRs also may recognize endogenous ligands such as degradation products of various extracellular matrix components released as a result of tissue damage called DAMPs. The recognition of DAMPs by TLRs may contribute to the development of inflammation and in some infections may lead to a greatly exaggerated inflammatory response. For instance, TLR4 increases the severity of the inflammatory response to H5N1 influenza virus infection by recognizing a DAMP rather than the virus itself. More specifically, acute lung injury caused by H5N1 virus produces endogenous oxidized phospholipids, which stimulate TLR4.[22] TLRs are expressed in different and important cells of the innate immune system including monocytes and macrophages, dendritic cells, neutrophils, vascular endothelial cells, and epithelial cells lining mucosal surfaces. Although some TLRs (e.g., TLR1, TLR2, TLR4, TLR5, and TLR6) are expressed on the cell surface, others (TLR3, TLR7, and TLR9) are found almost exclusively in intracellular compartments such as endosomes.[21]

TABLE 10.1

Toll-Like Receptors and Their Microbial Ligands

TLR	Ligand	Microbial Source
TLR1/TLR2 TLR2/TLR6	Lipoproteins Peptidoglycan Lipopolysaccharide Zymosan	Bacteria Gram-positive bacteria *Leptospira* Yeast
TLR3	Double-stranded RNA	Viruses
TLR4	Lipopolysaccharide	Gram-negative bacteria
TLR5	Flagellin	Various bacteria
TLR7/8	Single-stranded RNA	Viruses
TLR9	CpG DNA	Bacteria, protozoa

TLR, toll-like receptor.

Pathogens that have evaded cell surface or endosomal TLRs and have gained access to the cytosol are recognized by another group of PRRs called nucleotide-binding and oligomerization domain

(NOD) receptors and NOD-like receptors (NLRs).[23,24] Similar to TLRs, these receptors bind a variety of microbial products, including flagellin, bacterial exotoxins, and viral and bacterial DNA. Activation of NLRs is believed to require 2 signals and integrate the recognition of PAMPs with detection of cellular damage or stress (DAMPs). The activation of at least some of the NLRs induces assembly of a macromolecular inflammasome and activation of caspase 1, which catalyzes the proteolytic processing of pro-IL-1β to into mature active IL-1β.

The binding of microbial molecules to PRRs leads to the activation of intracellular signaling pathways. The predominant pathway used by TLRs leads to the activation of nuclear factor-κB (NF-κB), a nuclear transcription factor that initiates rapid changes in expression of several groups of genes (see Fig. 10.2). Most important are those encoding the following:

- Cytokines and chemokines (including the pyrogenic cytokines TNF-α, IL-1, IL-6, as well as IL-8; colony-stimulating factors; platelet-activating factor; among others)
- Enzymes involved in the degradation of extracellular matrix proteins
- Enzymes responsible for the production of small molecule mediators of inflammation such as arachidonic acid derivatives
- Proteins involved in microbial killing mechanisms

A subset of TLRs comprising TLR3, TLR7, and TLR9 recognizes nucleic acids derived mainly from viruses. In addition to production of proinflammatory cytokines, activation of these TLRs also leads to the production of type I IFNs that can induce proteins that interfere with viral replication.[21]

The engagement and activation of TLRs expressed on vascular endothelial cells also lead to increased expression of chemokines and adhesion molecules (selectins and integrin ligands).[25,26] Combined with the simultaneous upregulation of selectin ligands and integrins on leukocytes (also stimulated by TLR engagement), the result is adhesion of leukocytes to the vascular endothelium. Once these cells are firmly attached, they transmigrate across endothelial surfaces (i.e., extravasation) to the sites of inflammation. During extravasation, neutrophil degranulation occurs with the release of several proteolytic enzymes and toxic oxygen radicals that contribute to increased vascular permeability. Furthermore, activation of the complement system (classical and alternative pathways) and coagulation cascades (intrinsic and extrinsic pathways) occurs concurrently with cytokine stimulation. Release of the anaphylatoxins C3a and C5a promotes vascular abnormalities and neutrophil activation.

The cytokines and chemokines whose production is stimulated by PRR engagement in turn further amplify the inflammatory response:

- The cytokines IL-1, TNF-α, and IL-6 stimulate metabolism of arachidonic acid to form leukotrienes, thromboxane A_2, and prostaglandins (especially PGE_2 and PGI_2).
- IL-1, TNF-α, and IL-6 increase PGE_2 synthesis in the vascular and perivascular cells of hypothalamus, thus leading to generation of fever.[2–4]
- Granulocyte colony-stimulating factor increases production and release of neutrophils from the bone marrow to replace those consumed by inflammation, often leading to an increase in absolute neutrophil counts.
- IL-1 and TNF-α stimulate endothelial cells to synthesize secondary factors that contribute to the inflammatory process, including endothelial cell adhesion molecules, chemokines (IL-8, macrophage inflammatory protein-1α), and hemostatic tissue factor, as well as IL-1, PGI_2, and granulocyte-macrophage colony-stimulating factor.

The release of the hemostatic tissue factor by endothelial cells and macrophages appears to be pivotal in the activation of the coagulation cascade, which in turn can trigger further activation of the complement system. Together, the dysregulated activation of these pathways can lead to the disseminated intravascular coagulation seen in the systemic inflammatory response syndrome.[27] Platelets also are primed to interact with endothelium and aggregate in dense masses that interfere with tissue blood supply. Generalized endothelial cell activation is central to the pathogenesis of vascular injury and capillary permeability associated with acute inflammation that, when uncontrolled, can progress to shock and multiorgan dysfunction.[27]

Acute Phase Response

Primarily in response to IL-1 and IL-6, a structurally and functionally heterogeneous group of proteins known as acute phase response proteins changes their concentration in peripheral blood.[1,28] Some of these are *positive acute phase proteins* because they increase in concentration after antigenic stimuli. These proteins are synthesized mainly by the liver, and they include C-reactive protein (CRP), serum amyloid A, α_1-acid glycoprotein, α_1-antitrypsin, haptoglobin, ceruloplasmin, and fibrinogen. Other acute phase proteins are *negative acute phase proteins* because their plasma concentrations are reduced. Examples include albumin, prealbumin, retinol-binding protein, and transferrin. The exact functions of the acute phase proteins are not understood completely. CRP appears to be a pattern recognition molecule that typically binds to molecular configurations that either are exposed during cell death or are found on the surface of certain pathogens such as *Streptococcus pneumoniae*.[29] Ligand-bound or aggregated CRP efficiently activates the classical complement pathway through direct interaction with C1q and stimulates phagocytosis. This finding raises the possibility that CRP is involved in clearing of cellular debris from necrotic and apoptotic cells, but CRP also may give additional protection against certain microbes.

The acute phase responses provide a guide to the intensity of inflammation or the extent of tissue involvement. For instance, the rise in fibrinogen causes erythrocytes to form stacks (rouleaux) that sediment more rapidly than do individual erythrocytes. This is the basis for measuring erythrocyte sedimentation rate as a simple test for the magnitude of systemic inflammatory response regardless of the initiating stimuli.

The acute phase response also is associated with profound alterations in the use of carbohydrates, proteins, lipids, and minerals. These diverse cellular stressors may be advantageous during an infection by preferentially harming pathogens rather than the host.[30] The best-documented alterations in mineral use are decreased serum concentrations of iron and zinc caused by the uptake in hepatocytes and phagocytes, thus limiting their availability to pathogens.[31] Because of hypoferremia, reduction of red blood cell synthesis, and decreased red blood cell life span, mild but reversible anemia usually accompanies a significant acute inflammatory response.[1,32,33] The hypermetabolic state typically seen in patients with the systemic inflammatory response syndrome requires massive use of carbohydrate and lipid stores to meet energy needs, as well as use of amino acids from muscle tissue by the liver to produce glucose (gluconeogenesis). These changes are presumably provoked by cytokine-induced production of cortisol, insulin, glucagon, and growth hormone. Clinically, these abnormalities manifest as reactive hyperglycemia, substantial fluctuation in plasma concentrations of free fatty acids, hypertriglyceridemia, and negative nitrogen balance resulting from catabolism of amino acids. Many of these effects are mediated by TNF-α.

Regulatory Anti-Inflammatory Pathways

Excessive activation of the inflammatory responses described earlier can lead to extensive tissue damage and vascular injury, disseminated intravascular coagulation, and shock. To attenuate potential damage to the host, the inflammatory cascade stimulates modulating pathways that involve anti-inflammatory cytokines such as transforming growth factor-β (TGF-β), IL-4, and IL-10. TGF-β also stimulates production of extracellular matrix proteins and contributes to tissue remodeling after the resolution of inflammation. Natural inhibitors of inflammatory cytokines also exist.[34] For instance, many inflammatory cells including neutrophils and macrophages can shed their TNF receptors, which then bind free TNF and neutralize its proinflammatory activity. Similarly, the IL-1 system has unique pathways of negative regulation involving natural IL-1 receptor antagonists and the type II decoy receptor. Some anti-inflammatory cytokines (e.g., IL-4, IL-10) can simultaneously inhibit the production of IL-1 and stimulate the production of receptor antagonists and the decoy receptor. Thus an intricate network of positive and negative biofeedback loops operates during the course of a systemic inflammatory response, and the net balance determines the clinical expression and severity of disease.

Interaction of Innate and Adaptive Immune

Responses

In summary, the *immediate* inflammatory response to microbial invasion and tissue injury is controlled mainly by the innate immune system. This innate response is triggered by the binding of PAMPs and DAMPs to the PRRs (i.e., TLRs and NLRs) expressed in host cells. The subsequent intracellular signaling in host cells leads to increased expression of several groups of genes including those encoding pyrogenic and proinflammatory cytokines TNF-α, IL-1, and IL-6. TLR activation also causes upregulation of expression of the costimulatory molecules involved in antigen presentation (i.e., CD80/CD86). This leads to the enhancement of adaptive immunity that becomes more important in *later stages* of the inflammatory response. Anti-inflammatory pathways are activated simultaneously, and the net balance between proinflammatory and anti-inflammatory stimuli determines the magnitude and the outcome of the inflammatory response. Basic mechanisms of the inflammatory response are similar regardless whether the response is systemic or local. For instance, in bacterial meningitis, local production of cytokines within the subarachnoidal space in response to the presence of bacteria, or their cell wall components, induces disruption of the blood-brain barrier, increased vascular permeability, and chemotactic attraction of neutrophils to the meningeal site of microbial invasion.[35]

The effective coordination of adaptive and innate immunity eventually leads to the elimination of invading microbes. The absence of microbial stimulation causes cessation of the proinflammatory response and resolution of inflammation. At this stage, several cytokines and growth factors (including TGF-β) contribute to the repair of the damaged tissues. This process allows the host to return to and maintain a relative state of homeostasis until the next microbial challenge.

11

The Systemic Inflammatory Response Syndrome (SIRS), Sepsis, and Septic Shock

Judith A. Guzman-Cottrill, Louise Elaine Vaz

Sepsis remains a major cause of morbidity and mortality among children.[1-4] While the prevalence of pediatric sepsis has risen,[5,6] sepsis-associated mortality in children has decreased from 97% in 1966[7] to 8% to 12% by 2012.[5,6] In the United States, the estimated incidence annually is 0.89 cases per 1000 persons.[6] Although this represents a significant improvement over past decades, severe sepsis remains one of the leading causes of death in children.[7,8] A recent study estimates a median hospital stay of 17 days and total hospitalization cost of $77,446,[5] and $14.6 billion in health care expenditures in the US.[6]

In a seminal study, Watson and colleagues[9] analyzed the effects of age, birth weight, underlying disease, and microbiologic etiology on the incidence, mortality, and hospital costs of children who develop septicemia using 1995 hospital discharge and population data from seven states. Using the same databases, Hartman updated these estimates in 2005.[6] The incidence is highest in newborns (9.70 per 1000) and falls significantly in older children (0.48 per 1000 in 10- to 14-year-olds). An increase in prevalence among very low birth weight infants was noted from 1.8 cases per 1000 births in 1995 to 4.6 cases per 1000 in 2005. Underlying comorbidities varied by age; however, neuromuscular, cardiovascular, and respiratory were the most common comorbidities in all years. Endocarditis and central nervous system infections had the highest case-fatality rates (16.7% and 15.2%, respectively), whereas genitourinary and wound and soft tissue infections had the lowest (3.7% and 3.9%, respectively).[6]

Global estimates for sepsis are limited; however, the Sepsis Prevalence, Outcomes, and Therapies (SPROUT) study recently used prospective point prevalence estimates among 128 sites in 26 countries.[10] Prevalence was noted to be 8.2%, with hospital mortality of 25%, and did not differ by age or between developed and resource limited countries. Additional patient characteristics from this international study are noted in Table 11.1.

TABLE 11.1

Characteristics of Patients with Severe Sepsis

Characteristic	**Value**
Age in years	3.0 (0.7–11.0)
Male sex, *n* (%)	302 (53.3%)
Race/ethnicity, *n* (%)	
White	245 (43.2)
Hispanic	97 (17.1)
Black	79 (13.9)
Asian	75 (13.2)
Other	39 (6.9)
Unknown	32 (5.6)
Comorbid condition(s), *n* (%)

Definitions

An international panel of experts in the fields of adult and pediatric septicemia and clinical research in 2005 proposed the first set of specific definitions and criteria for the components of the sepsis continuum that can be applied consistently in the pediatric population.[11] These definitions were used again in the international guidelines for management of sepsis and septic shock.[12] The consensus definitions for systemic inflammatory response syndrome (SIRS), infection, sepsis, severe sepsis, septic shock, and multiple organ dysfunction syndrome in children are listed in Box 11.1 and Table 11.2. It is important to recognize that these definitions were meant for use in the design, conduct, and analysis of large, multicenter, international therapeutic trials rather than as a clinical tool at the bedside. It is clear that, given the intraindividual and interindividual differences in the time course of disease progression, these definitions often have limited clinical utility.[13] Other vital sign ranges (such as used by the Pediatric Advanced Life Support septic shock guidelines) may be clinically useful to help guide diagnostic and therapeutic decisions.[14]

Box 11.1

Definitions of Systemic Inflammatory Response Syndrome, Infection, Sepsis, Severe Sepsis, and Septic Shock[1]

Systemic Inflammatory Response Syndrome (SIRS)

Presence of two or more of the following criteria, one of which must be abnormal temperature or leukocyte count:

- Core temperature by rectal, oral, or central catheter probe of >38.5°C or <36°C

- Tachycardia, defined as a mean heart rate >2 SD above normal for age in the absence of external stimulus, chronic drugs, or painful stimuli; or otherwise unexplained persistent elevation over a 0.5- to 4-hour time period or for children <1 year old: bradycardia, defined as a mean heart rate <10th percentile for age in the absence of external vagal stimulus, β-blocker drugs, or congenital heart disease; or otherwise unexplained persistent depression over a 0.5-hour time period

- Mean respiratory rate >2 SD above normal for age or mechanical ventilation for an acute process not related to underlying neuromuscular disease or the receipt of general anesthesia

- Leukocyte count elevated or depressed for age (not secondary to chemotherapy-induced leukopenia) or >10% immature neutrophils

Infection

Suspected or proven (by positive culture, tissue stain, or polymerase chain reaction test) infection caused by any pathogen or a clinical syndrome associated with a high probability of infection

Evidence of infection includes positive findings on clinical examination, imaging, or laboratory tests (e.g., white blood cells in a normally sterile body fluid, perforated viscus, chest radiograph consistent with pneumonia, petechial or purpuric rash, or purpura fulminans)

Sepsis

SIRS in the presence of or as a result of suspected or proven infection

Severe Sepsis

Sepsis plus the following: cardiovascular organ dysfunction, acute respiratory distress syndrome (ARDS), or two or more other organ dysfunctions

Septic Shock

Sepsis and cardiovascular organ dysfunction

Distributive (Warm) Shock

Decreased systemic vascular resistance and elevated cardiac output noted by fast capillary refill, bounding pulses, warm and dry extremities, and wide pulse pressure

Cold Shock

Increased systemic vascular resistance with decreased cardiac output noted by delayed capillary refill, diminished pulses, and mottled and cool extremities

TABLE 11.2

Age-Specific Abnormal Vital Signs and Laboratory Values[a]

Age Group	Heart Rate (beats/min)		Respirations (breaths/min)	Systolic Blood Pressure (mm Hg)	Peripheral Leukocyte Count (Leukocytes × $10^3/mm^3$)
	Tachycardia	Bradycardia	Tachypnea	Low	High/Low
0 days to 1 wk	>180	<100	>50	<65	>34

1 wk to 1 mo	>180	<100	>40	<75	>19.5 or <5
1 mo to 1 yr	>180	<90	>34	<100	>17.5 or <5
2 to 5 yr	>140	NA	>22	<94	>15.5 or <6
6 to 12 yr	>130	NA	>18	<105	>13.5 or <4.5
13 to <18 yr	>110	NA	>14	<117	>11 or <4.5

[a] Lower values for heart rate, leukocyte count, and systolic blood pressure are for the 5th percentile, and upper values for heart rate, respiration rate, or leukocyte count are for the 95th percentile.

NA, not applicable.

Etiology

Several factors influence the potential pathogens causing septicemia in children, including age, host immune status, presence of an indwelling catheter, and geographic location at the time of infection. In addition, organisms causing community-onset infections differ from those acquired in the hospital setting. During the neonatal period, common bacterial causes include group B *Streptococcus* and enteric bacilli, such as *Escherichia coli.* Other less common pathogens include enterococci, *Listeria monocytogenes, Staphylococcus aureus* (including methicillin-resistant *Staphylococcus aureus* [MRSA]), nontypable *Haemophilus influenzae,* and *Streptococcus pneumoniae*. Advances in neonatology and survival of very low birth weight infants affect the epidemiology of hospital-associated neonatal sepsis. The use of central venous lines and other foreign bodies further predisposes these already compromised neonates to pathogens such as coagulase-negative staphylococci, *S. aureus* (including MRSA), other gram-negative bacilli, and *Candida* spp. Rigorous application of bundles of infection control practices can reduce dramatically the incidence of coagulase-negative staphylococci bloodstream infection in neonatal intensive care[15] (see Chapter 100). Viral neonatal sepsis may be clinically indistinguishable from bacterial disease. Viral pathogens include herpes simplex virus, adenovirus, enteroviruses, respiratory syncytial virus, and influenza virus.

Beyond the neonatal period, *S. pneumoniae* and *Neisseria* *meningitidis* are common causes of sepsis in otherwise healthy children. *Haemophilus influenzae* type b (Hib) should be considered in the incompletely vaccinated child. Before the Hib vaccine, there were estimates of 20,000 cases per year. This has since been reduced to less than 700 per year, with the largest burden in children younger than 5 years and adults 65 years and older.[16,17] Since the routine administration of the heptavalent pneumococcal conjugate vaccine (PCV7) in 2000, the overall incidence of invasive pneumococcal disease due to vaccine serotypes in children younger than 5 years declined by 97%.[18] Universal infant immunization with PCV13 in 2010 further reduced invasive pneumococcal disease, without evidence to date of replacement serotype invasive disease.[19] Remaining cases of invasive pneumococcal disease currently are occurring disproportionately in children with underlying conditions and with a variety of nonvaccine serotypes.[20]

Other organisms causing sepsis include *S. aureus* and *Streptococcus pyogenes*, which also can cause toxic shock syndrome, as well as *Salmonella* spp. and rickettsiae in certain geographic regions (e.g., Rocky Mountain spotted fever). Malaria and dengue fever also can cause sepsis. In hospitalized infants and children with indwelling central venous lines, coagulase-negative staphylococci, *S. aureus*, gram-negative bacilli, and *Candida* spp. are important causes of sepsis related to central-line–associated bloodstream infection. Infections with multidrug-resistant organisms are an increasing, particularly those due to gram-negative organisms (carbapenemase-resistant strains, extended-spectrum β-lactamase [ESBL] strains,) and enterococci (vancomycin resistant).

Children with underlying immunodeficiency can have septicemia caused by the same pathogens as healthy children; however, some conditions predispose the immunocompromised host to additional organisms. Neutropenic oncology patients with mucositis are at risk for sepsis due to the Enterobacteriaceae (or other gram-negative bacilli such as *Pseudomonas aeruginosa*) and gram-positive organisms, including α-hemolytic streptococci. Viridans group streptococci are an important cause of sepsis in the neutropenic oncology population, often with associated acute respiratory distress syndrome (ARDS).[21,22] Prolonged neutropenia and recent antibiotic use can increase the risk for fungal sepsis. As most oncology patients have an indwelling central venous catheter, they also remain at risk for the typical central-line–associated bloodstream infection pathogens. Patients with acquired immunodeficiency syndrome (AIDS) are at higher risk for bacteremia due to *S. pneumoniae, P. aeruginosa, S. aureus,* and typable *H. influenzae*. Patients with anatomic or functional asplenia (including sickle cell disease) are at increased risk for sepsis caused by encapsulated organisms such as *S. pneumoniae, Salmonella* spp., *H. influenzae, N. meningitidis,* and *Capnocytophaga canimorsus* (associated with dog or cat exposure).

Culture-negative sepsis occurs in 30% to 75% of children with sepsis, reflecting a host response to bacterial components, a result of antibiotic treatment before obtaining cultures, or uncultivated organisms (e.g., rickettsiae, certain fungi, and viruses). Newer multiplex polymerase chain reaction assays may improve the rate of organism detection.[23,24]

Pathophysiology

If a microbe gains access to the intravascular compartment, the host activates defensive mechanisms. Transient bacteremia without significant clinical consequences occurs commonly in healthy children. Depending on the age and immunocompetence of the patient, the virulence and number of pathogens in the blood, and the timing and nature of a therapeutic intervention, the host's systemic inflammatory response ensues and can progress independently despite successful eradication of the microbe. Although infection is a major cause of SIRS, a number of other entities, including trauma, ARDS, neoplasm, burn injury, and pancreatitis, also are recognized causes.

Most pathophysiologic consequences of the sepsis syndrome result from an imbalance between proinflammatory and anti-inflammatory mediators in combination with microbial toxins.[25] In children, severe sepsis arises from coordinated activation of the innate immune response.[26] This response, triggered by diverse pathogens, is multifaceted.[25-27] When triggered, the response leads to secretion of proinflammatory and anti-inflammatory cytokines, activation and mobilization of leukocytes, activation of coagulation and inhibition of fibrinolysis,[28,29] and increased apoptosis.[30] As a result of coagulation activation, generation of thrombin promotes fibrin deposition in the microvasculature and also exacerbates ongoing inflammation by direct and indirect mechanisms.[25] Although evolutionarily designed to limit microbial dissemination, overly exuberant innate inflammatory processes can be detrimental, resulting in cardiac dysfunction, vasodilation, capillary injury, and microvascular and macrovascular thromboses. Despite antimicrobial therapy and intensive supportive care, these processes frequently lead to organ dysfunction, thrombotic complications, longterm neurologic morbidity, or death.[1,31]

The clinical manifestations are the result of systemic inflammation and include abnormal temperature regulation, flushed warm skin, widened pulse pressure, tachycardia, tachypnea, metabolic acidosis (elevated serum lactate, decreased base excess), renal or hepatic dysfunction, thrombocytosis, and leukocytosis. As the syndrome progresses, multiorgan failure, including acute respiratory failure, hypotension, myocardial failure, decreased neurologic function, oliguric or anuric renal failure, hepatic failure, leukopenia, anemia, and thrombocytopenia, can ensue and can lead to death.

Clinical and Laboratory Findings

Fever, tachycardia, and tachypnea are the most common physiologic abnormalities associated with sepsis, even though they are insensitive and nonspecific. Other clinical signs include decreased tone, diminished activity, pale or grey skin color, prolonged capillary refill time, and poor feeding or sucking.[32] Biochemical markers of inflammation may one day prove to be more objective and reliable than physiologic findings; however, no biochemical marker has been confirmed to be robust enough to use for the definitive diagnosis of sepsis or for tracking response to therapy and disease progression. In terms of septic shock, early recognition should be done by clinical examination because there are no reliable biochemical tests available to date.[12] Nonetheless, a rapid and reliable clinical or biologic marker would be invaluable because early treatment with antibiotics and fluid resuscitation has been clearly demonstrated to reduce both morbidity and mortality.[12,33]

Clinical Signs

The earliest clinical sign of infection is age-dependent change in body temperature.[34] In immune-competent children, the earliest sign is fever. In immune-compromised children and premature infants, the earliest sign can be hypothermia or fever.[34] Fever in association with changes in a child's behavior, such as an infant's loss of smiling or playfulness (especially after fever has been controlled with antipyretic therapy), is a sign of serious infection, which can benefit from antibacterial, antiviral, or antifungal therapy.[35-37]

Tachycardia is a useful sign of sepsis in the neonate born at term,[38] as is tachycardia or tachypnea in older children.[34] Fever can account for some tachycardia, as each 1°C increase can result in an increase in heart rate of 10%; however, the heart rate and respiratory rate should become normal for age when fever is controlled with antipyretic therapy or falls spontaneously.[34] Heart rate higher than 150 beats/min in children and higher than 160 beats/min in infants and respiratory rates higher than 50 breaths/min in children and higher than 60 breaths/min in infants are associated with increased mortality risk and commonly presage the development of septic shock.[11] A minimal mean arterial pressure of more than 30 mm Hg is considered the absolutely lowest tolerable blood pressure in the extremely premature infant.[12,39] Specific hemodynamic abnormalities in the emergency department have been associated with increasing mortality (percentages in parenthesis): eucardia (1%), tachycardia/bradycardia (3%), hypotension with capillary refill less than 3 seconds (5%), normotension with capillary refill greater than 3 seconds (7%), and hypotension with capillary refill greater than 3 seconds (33%).[12,14]

Laboratory Findings

Numerous biologic markers of sepsis in children have been studied, but none has made its way to complete acceptance in clinical practice based on prospective clinical trials and evidence-based criteria.[34,40,41] Biomarkers that are commonly used diagnostically, clinically, and prognostically include the total peripheral white blood cell count,[42] platelet count, erythrocyte sedimentation rate, lactate,[43,44] procalcitonin,[45-48] C-reactive protein,[49-52] interleukin-6,[53-56] base excess/base deficit, glucose, and organ-specific markers (e.g., blood urea nitrogen, creatinine, alanine aminotransferases, coagulation). None is completely sensitive or specific.[57,58] There are many types of biologic markers currently under development that may prove to be more accurate in screening, diagnosing, and determining the response to therapy during infection and sepsis. These include tests such as serum amyloid A level,[57] rapid antigen assays,[59] polymerase chain reaction,[60-62] genomic testing (for guiding therapy and determining host response),[63-65] and proteomic profiling (for identification of differentially expressed proteins and peptides).[66-69] Combinations of markers may improve sensitivity and specificity.[70] A pediatric sepsis biomarker risk model (PERSEVERE), using a combination of biomarkers, recently has been shown to identify children with septic shock at risk for death and more severe illness.[71-73]

Management

Antimicrobial Therapy

Empiric therapy for suspected sepsis should be targeted toward the likely causative pathogens (Table 11.3). Important considerations when selecting a regimen include the child's age, community versus hospital acquisition, host immune status, and penetration into tissues and compartments (such as central nervous system). Knowledge of bacteria susceptibility patterns in the community and institution is essential; in US cities, rates of community-acquired MRSA isolates can be as high as 76%.[74] Vancomycin should be included in the empiric regimen if the clinical syndrome is compatible with staphylococcal infection and MRSA is recovered more than sporadically in the geographic area. If *E. coli* or *Klebsiella* spp. (or other gram-negative bacilli in certain hospital settings) is isolated, the organism should be tested for ESBL production. Carbapenems are the treatment of choice for serious infections with ESBL-producing organisms.[75] Infections caused by carbapenem-resistant Enterobacteriaceae are increasing worldwide and have been reported in pediatric populations.[76,77] Continued local and regional surveillance for these multidrug-resistant pathogens is critical at the local, regional, and national level.

TABLE 11.3

Suggested Initial Antimicrobial Agents for Empiric Therapy in Infants and Children with Suspected Sepsis

Age or Clinical Situation	**Antimicrobial Agents**[a]
Neonate (community onset)	Ampicillin *plus* gentamicin
Neonate (hospital onset)	Vancomycin, *plus* gentamicin *or* cefotaxime
Neonatal HSV infection	Acyclovir
Child (community onset)	Cefotaxime *or* ceftriaxone, *plus* vancomycin
Child (hospital onset)	Vancomycin, *plus* antipseudomonal penicillin *or* ceftazidime *or* cefepime *or* carbapenem[b]
Coverage for intra-abdominal or genitourinary sources	Cefepime, ceftazidime, ciprofloxacin *or* levofloxacin, *plus* metronidazole *or* piperacillin-tazobactam *or* carbapenem
Skin or soft tissue involvement	Vancomycin *or* semisynthetic penicillin, *plus* clindamycin
Toxic shock syndrome	Vancomycin *or* semisynthetic penicillin, *plus* clindamycin
Immunosuppressed, cystic fibrosis	Vancomycin *plus* cefepime *or* ceftazidime, *plus* gentamicin *or* carbapenem (if ESBL-producing organism suspected)
Immunocompromised with persistent fever	*Add* liposomal amphotericin *or* echinocandin *or* voriconazole
Tick-borne diseases: Rocky Mountain spotted fever, ehrlichiosis	Doxycycline (for any age)

[a] Antimicrobial therapy should be modified as laboratory data are available and based on clinical course.

[b] Antimicrobial therapy should be based on patient-specific risk factors and local antimicrobial susceptibility therapy patterns (see text).

ESBL, extended spectrum β-lactamase; HSV, herpes simplex virus.

When the causative organism is isolated and antibiotic susceptibilities are available, antimicrobial therapy should be adjusted appropriately. When possible, broad-spectrum agents (such as vancomycin and carbapenems) should be discontinued to minimize the emergence of multidrug-resistant organisms.

Prompt initiation and appropriate choice of antibiotics are critical in the management of sepsis, and both concepts have been shown to improve outcomes in adults.[12,78-80] A recent pediatric study identified delayed antimicrobial therapy as an independent risk factor for mortality and prolonged duration of organ dysfunction. Weiss and associates determined that more than a 3-hour delay from sepsis recognition to initiation of therapy and first appropriate antimicrobial therapy was associated with higher mortality[81]; the odds ratio for pediatric intensive care unit mortality was 3.92 (95% confidence interval [CI], 1.27–12.06) and 3.59 (95% CI, 1.09–11.76), respectively.

Supportive Care

Effective treatment of sepsis and septic shock is dependent on prompt recognition and initiation of supportive as well as specific therapy. The basic principles of initial critical care include ensuring adequate airway patency, gas exchange (breathing), and circulation (the so-called ABCs). The interventions required to achieve these goals depend on the specific physiologic state of the patient at the time of presentation. Shock that occurs during sepsis results from decreased intravascular volume, maldistribution of intravascular volume, or impaired myocardial function, all of which can occur at different times during the course of septic shock.[82] Children with sepsis who receive early aggressive fluid resuscitation (>40 mL/kg in the first hour with isotonic intravenous fluids) demonstrate improved survival without increased risk for noncardiogenic pulmonary edema or ARDS.[83,84]

Determination of when, what type of, and how much pharmacologic support is needed in a patient with septic shock requires careful consideration of many factors. These factors include the patient's clinical state (e.g., capillary refill time, urine output, peripheral versus core temperature gradient), information obtained from monitoring devices (heart rate, blood pressure, central venous pressure, pulmonary artery pressure, cardiac output, stroke volume, and systemic vascular resistance), and knowledge of basic drug effects (including dopamine, norepinephrine, epinephrine, and phenylephrine) in the setting of septic shock.

Septic shock causes multisystem organ dysfunction, and it is important to evaluate and manage abnormalities in other organ systems, including the kidney and gastrointestinal tract. Patients with acute renal failure may require renal replacement therapy. The gastrointestinal tract is vulnerable to disturbances such as hemorrhage, ileus, brush border atrophy, and translocation of enteric organisms into the blood. Additionally, early institution of nutritional support, particularly enteral feeding, can ameliorate gastrointestinal atrophy and improve function of multiple organ systems.[85]

Maintaining tight control of blood glucose level has been shown to be beneficial in some studies in critically ill adult patients, but the current evidence does not adequately address this issue in the pediatric population.[86,87]

Intravenous Immunoglobulin Therapy

Immunoglobulin for intravenous use (IGIV) can be regarded as a treatment method that seeks to improve host defense. Although plasma immunoglobulin concentration can be reduced in patients with sepsis, the use of IGIV therapy is not supported by randomized clinical trials. A small nonblinded study of 21 patients with streptococcal toxic shock syndrome showed a reduced mortality (6% versus 34%, $P = 0.02$).[88] Results of the International Neonatal Immunotherapy Study, which enrolled 3493 infants, also demonstrated no effect on the outcomes of suspected or proven neonatal sepsis; these results are echoed in a *Cochrane Review*.[89-92] For patients with toxic shock syndrome, IGIV may have clinical utility.

Corticosteroids

Adrenal failure is common in critical illness and in particular in vasopressor-dependent septic shock. High baseline total serum cortisol, together with a low response to a corticotropin stimulation test, is correlated with a poor outcome in sepsis.[93] Several studies in children and adults with septic shock have demonstrated abnormalities of control of adrenal corticosteroid secretion over the course of illness.[94,95]

Various randomized controlled trials comparing administration of hydrocortisone to placebo have been performed in septic shock. There is general agreement that hydrocortisone supplementation improves the hemodynamic condition of vasopressor-dependent septic shock.[96] What remains more controversial is the definition of adrenal insufficiency, the optimal dose and timing of steroid supplementation, whether this should then be tapered slowly, and the effect of steroid supplementation on outcome.[97] Although evidence is lacking regarding how to measure adrenal insufficiency in children, it is advised to obtain a baseline serum cortisol or adrenocorticotropin hormone stimulation test before steroid administrations.[97] A multicenter, randomized, placebo-controlled trial of 499 patients with septic shock[98] found that hydrocortisone did not improve survival overall or in the subgroup of patients who did not have a response to corticotropin, although shock was reversed more quickly in the hydrocortisone-treated group than in the placebo group.

Future Considerations

The publication of the human genome will allow for rapid advances in genomics and proteomics. The possibilities for individualized drug treatment of patients with sepsis, related to their genotype, may become reality. New innovations, such as the pediatric sepsis biomarker risk model (PERSEVERE),[71,72] may allow for targeted therapy and improved early risk stratification of children with sepsis.

Current research focused on sepsis management includes anticytokine therapy such as anti–tumor necrosis factor-α,[99,100] anticoagulant therapies such as antithrombin,[101] and hemofiltration through continuous renal replacement therapy. The recently completed IVOIRE (hIgh VOlume in Intensive Care) hemofiltration study is a prospective randomized multicenter trial comparing two treatments in adults with septic shock complicated with acute renal failure.[102] One group will be treated by early high volume hemofiltration (70 mL/kg/h) and the second group by standard volume hemofiltration (35 mL/kg/h), with one-month mortality as the primary outcome measured. The results of this study may clarify the value of continuous renal replacement therapy in sepsis and acute kidney injury.

The development of an antiendotoxin vaccine targeted against core lipopolysaccharide structures of gram-negative bacteria has not led to protective efficacy for sepsis.[103,104] Because antibiotic resistance among gram-negative bacteria has reached critical levels (and development of novel therapeutics is lagging), antiendotoxin vaccines against sepsis should be readdressed.[105] Until then, sepsis management remains dependent on early administration of appropriate antimicrobial therapy, resuscitation by a practiced protocol, and “source control” when identified.[12]

Hemophagocytic Lymphohistiocytosis and Macrophage Activation Syndrome

Hayley A. Gans, David B. Lewis

Hemophagocytic Lymphohistiocytosis

Hemophagocytic lymphohistiocytosis (HLH) is a clinical syndrome characterized by the accumulation of activated T lymphocytes and well-differentiated macrophages (histiocytes) in the bone marrow, lymph nodes, liver, spleen, and, often, the central nervous system (CNS). HLH is typified by fever, hepatosplenomegaly, peripheral blood cytopenias, and, most characteristically, hemophagocytosis, that is, the presence of intact red blood cells, leukocytes, platelets, or their precursors within infiltrating macrophages of the liver, spleen, bone marrow, and the CNS.[1,2] Most cases of HLH appear to be due to lymphocyte hyperactivation, particularly $CD8^+$ T lymphocytes,[3] with cytokine hypersecretion resulting in systemic mononuclear phagocyte activation, inflammation, coagulopathy, and, potentially, multiorgan failure.

HLH is divided into primary and secondary forms.[4] In the primary form, HLH is the predominant presenting feature of a small group of genetic disorders, including familial hemophagocytic lymphohistiocytosis (FHL).[3] Systemic infections are a precipitant of the hemophagocytic syndrome in many primary cases.[1,5] Secondary HLH encompasses all other causes and also most often is triggered by systemic infections, especially in immunocompromised hosts,[6–8] or by untreated hematologic malignancies.[4] The macrophage activation syndrome (MAS), which occurs in rheumatologic autoinflammatory and autoimmune disorders, has some pathologic similarities to HLH[9] but is treated differently and is discussed at the end of this chapter.

Etiology and Incidence

Primary Hemophagocytic Lymphohistiocytosis

Classic FHL, which was first reported in 1952,[10] accounts for approximately 25% of all HLH cases worldwide. FHL is estimated to affect 1 in 50,000 live births in northern Europe[1] and likely occurs at a higher frequency in countries where consanguinity is common.[11] One study estimated the overall prevalence of HLH to be 1.07 per 100,000 persons younger than 18 years.[12] There are five types of FHL but only four genetically defined autosomal recessive (AR) causes of FHL[3,13] (accounting for 90% of FHL cases) due to mutations in the genes (indicated in italics) encoding perforin (*PRF1*; FHL2, 20% to 40% of FHL), Munc13-4 (*UNC13D*; FHL3, 20% to 25% of FHL), syntaxin 11 (*STX11*; FHL4, 14% to 21% of FHL), and syntaxin-binding protein 2 (*STXB2*; FHL5) (Table 12.1), all of which play critical roles in cell-mediated cytotoxicity.[14–20] The AR genetic defect for FHL1 is unknown.[13] In FHL, HLH typically is fulminant and develops in the first few months of life or even in utero.[21] HLH rarely can manifest first in adulthood, especially in cases in which hypomorphic FHL mutations preserve some protein function.[13] In addition to HLH, FHL5 can manifest with hypogammaglobulinemia, bleeding, or colitis.[22]

TABLE 12.1

Classification of Pediatric Hemophagocytic Lymphohistiocytosis

PRIMARY HLH		
Familial HLH	**Chromosome**	**Protein/Gene**
FHL1	9q21.3-22	Unknown
FHL2	10q22	Perforin IPRF1
FHL3	17q25.1	MUNC13-4/*UNC13D*
FHL4	6q24	Syntaxin-11/*STX11*
FHL5	19p13.3-p13.2	MUNC18-2/*STXBP2*
Immunodeficiency Disease		
CHS-1	1q42.1-q42.2	*LYST*
XLP disease		
(XLP1)	Xq25	SAP/*SH2D1A*
(XLP2)	Xq25	XIAP/*BIRC4*
HPS	5q14.1	*AP3B1*
GS type 2	15q21	*RAB27A*
ITK	5q31-q32	*ITK*/ITK
CD27 deficiency	12p13	*CD27*/CD27
SECONDARY HLH		
Infections	**Frequent Inciting Agents**	
Viral	Adenovirus, enteroviruses, herpesviruses (EBV, CMV, HSV, HHV-6, HHV-8, VZV), HIV (including acute infection), influenza (including H5N1), measles, parvovirus B19	
Bacterial	*Mycobacterium tuberculosis*, *Brucella*, *Coxiella*, rickettsioses, gram-negative or gram-positive bacteremia	
Parasitic	*Plasmodium* spp., *Leishmania* spp.	
Fungal	*Histoplasma capsulatum*, *Penicillium* sp., *Fusarium* sp.	
Noninfectious Categories		
Therapy	ART, phenytoin, other anticonvulsants, BMT, solid organ transplant, chemotherapy	
Oncologic (as presenting feature)	Lymphomas, pre–B-cell ALL	
Rheumatologic	JIA, SLE, Kawasaki disease	

ALL, acute lymphoblastic leukemia; BMT, bone marrow transplantation; CHS, Chédiak-Higashi syndrome; CMV, cytomegalovirus; EBV, Epstein-Barr virus; FHL, familial hemophagocytic lymphohistiocytosis; GS, Griscelli syndrome; ART, antiretroviral therapy; HIV, human immunodeficiency virus; HHV-6, human herpesvirus 6; HHV-8, human herpesvirus 8; HLH, hemophagocytic lymphohistiocytosis; HPS, Hermansky-Pudlak syndrome; HSV, herpes simplex virus; JIA, juvenile idiopathic arthritis; SLE, systemic lupus erythematosus; XLP, X-linked lymphoproliferative syndrome; VZV, varicella-zoster virus.

Adapted from Janka G, Zur Stadt U. Familial and acquired hemophagocytic lymphohistiocytosis. Hematol (Am Soc Hematol Educ Program) 2005;82–88; Janka G, Imashuku S, Elinder G, et al. Infection- and malignancy-associated hemophagocytic syndromes. Secondary hemophagocytic lymphohistiocytosis. Hematol Oncol Clin North Am 1998;12:435–444; and Janka G, Lehmberg K. Hemophagocytic syndromes: an update. Blood Rev 2014;28:135-42.

Several primary immunodeficiency disorders are associated with high rates of HLH, which all have in common defects in genes encoding proteins involved with cytotoxicity (see Table 12.1). In addition, a susceptibility to Epstein-Barr virus (EBV) disease and HLH is seen specifically with four mutations. First is X-linked lymphoproliferative (XLP) disease, which has two subsets.[23] XLP1 disease (SAP/*SH2D1A* deficiency) only affects males and usually presents in association with primary EBV infection, with about 60% of cases developing fulminant HLH.[24] In contrast to FHL, hypogammaglobulinemia, often present before EBV infection,[24] is frequent, as is the rapid development of EBV-related lymphoproliferative disease or lymphomas. XLP2 disease (XIAP/*BIRC4* deficiency)[25,26] only affects males and can manifest similarly to FHL. XLP2 also can have a more delayed, mild, or recurrent course, with recovery without cytotoxic chemotherapy.[26] In contrast to XLP1 disease, EBV-related lymphoproliferative disease or lymphoma is infrequent, and it is not clear whether hypogammaglobulinemia frequently occurs before the onset of HLH.[25,26]

Analysis of a cluster of EBV-driven HLH cases lead to the discovery of interleukin-2–inducible T-cell kinase *(ITK)* gene mutations in several individuals, which was associated with a poorer survival despite therapy.[27] In addition, defects in CD27, a member of the tumor necrosis factor receptor family, have also been reported in several patients with EBV-associated HLH.[28]

Unrelated to EBV susceptibility are a group of primary immunodeficiencies that have defects that predispose to HLH. These include Griscelli syndrome type 2 (AR *RAB27A* gene deficiency), which typically manifests as early-onset HLH in manner indistinguishable from FHL.[29] Melanosome transport also is defective, resulting in partial albinism and the hair having a characteristic silvery sheen.[3] In addition, in Chédiak-Higashi syndrome (AR *LYST* gene deficiency), HLH frequently develops during infancy or childhood.[30] Chédiak-Higashi syndrome readily is distinguished from other forms of primary HLH by oculocutaneous albinism, dysfunctional neutrophils with giant inclusions, and platelet dysfunction.[31]

Among the same family as Griscelli and Chédiak-Higashi syndromes is Hermansky-Pudlak syndrome type 2 (*AP3B1* gene deficiency), which has been described in 3 patients and includes oculocutaneous albinism, bleeding, recurrent infection, and neutropenia, and was accompanied by lethal HLH in 1 patient.[32]

Secondary Hemophagocytic Lymphohistiocytosis

The incidence of secondary HLH has not been defined but is likely underreported. Secondary HLH most often is triggered by severe or prolonged infections in immunocompromised patients (see Table 12.1), particularly those with severe acquired immunodeficiency,[33] such as that due to HIV/AIDS,[34] cancer chemotherapy,[35] or potent immunosuppression. However, secondary HLH is reported in immunocompetent hosts and also can be a complication of severe infection in patients with primary immunodeficiencies other than those that are causes of primary HLH, including chronic granulomatous disease,[36,37] severe combined immunodeficiency,[38,39] DiGeorge syndrome (22q11.2 deletion),[40] Wiskott-Aldrich syndrome,[41] and X-linked agammaglobulinemia.[42] In the immunocompetent host, secondary HLH originally was considered to be mainly a complication of primary EBV infection in previously healthy older children; however, it is now appreciated that HLH can occur in all ages in association with severe infections with a wide variety of pathogens (see Table 12.1).[7,8,43] Common non-EBV viral triggers include infections with other herpesviruses (e.g., cytomegalovirus, human herpesvirus type 6 [HHV-6], HHV-8), adenovirus, dengue, enterovirus, influenza A,[44] and parvovirus B19. There are case reports of many other types of viral infection that also have been associated with HLH, suggesting that HLH potentially can complicate any severe systemic viral infection. Severe bacterial infections, particularly those involving the reticuloendothelial system (e.g., typhoid fever, rickettsial diseases, brucellosis, and disseminated *Mycobacterium tuberculosis*)[8] are frequent precipitants of HLH, and systemic fungal infections (e.g., *Histoplasma* and *Penicillium* spp. infection) are recognized causes. Visceral leishmaniasis, which has been misdiagnosed as FHL,[45] and malaria are frequent protozoal triggers.[8] As the recognition of HLH increases, so do the reports of infectious associations. This indicates that the disorder can be the end result of marked immune activation from any inciting event.

Rarer noninfectious conditions associated with secondary HLH in children (see Table 12.1) include lymphoid malignancies,[46,47] antiretroviral therapy for HIV, antiepileptic drug therapy, acute allograft rejection, graft-versus-host disease (GvHD; including by maternal T-lymphocyte engraftment in infants with severe combined immunodeficiency),[39] hemolytic anemia, and certain inherited metabolic disorders (e.g., lysinuric protein intolerance).

Pathogenesis

In primary HLH, most of the identified genetic defects compromise the ability of T lymphocytes and natural killer (NK) cells to kill target cells through the usual pathway of the secretion of perforin and granzymes from intracellular cytotoxic granules (Fig. 12.1). Under normal conditions, antigenically naïve $CD8^+$ T lymphocytes acquire their cytotoxic granules after activation and differentiation into effector cells, whereas newly produced NK cells emerge from the bone marrow containing these granules. Cytotoxic granules are released by $CD8^+$ T lymphocytes after their surface αβ T-cell receptors (TCRs) are engaged by antigenic peptide–major histocompatibility (MHC) complexes on the infected target cell, whereas NK-cell granule release occurs when the NK cells encounter infected target cells that lack MHC class I expression. Cell-mediated cytotoxicity requires the concerted activity of the LYST, Rab27a, MUNC13-4, syntaxin 11, and MUNC18-2 proteins for the intracellular maturation, trafficking, prerelease priming, and exocytosis of cytotoxic granules. The end result is apoptosis and clearance of the infected cell and microbe-derived antigen and termination of the immune response; genetic mutations encoding these proteins result in ineffective cell clearance and persistent immune activation in Chédiak-Higashi syndrome, Griscelli syndrome type 2, FHL3, FHL4, and FHL5, respectively.[3] The release of perforin, which is defective in FHL2, perforates the target cell membrane, allowing the cytoplasmic entry of granzymes that trigger target cell apoptosis (see Fig. 12.1).[48,49] It is not yet known how XIAP deficiency promotes HLH.

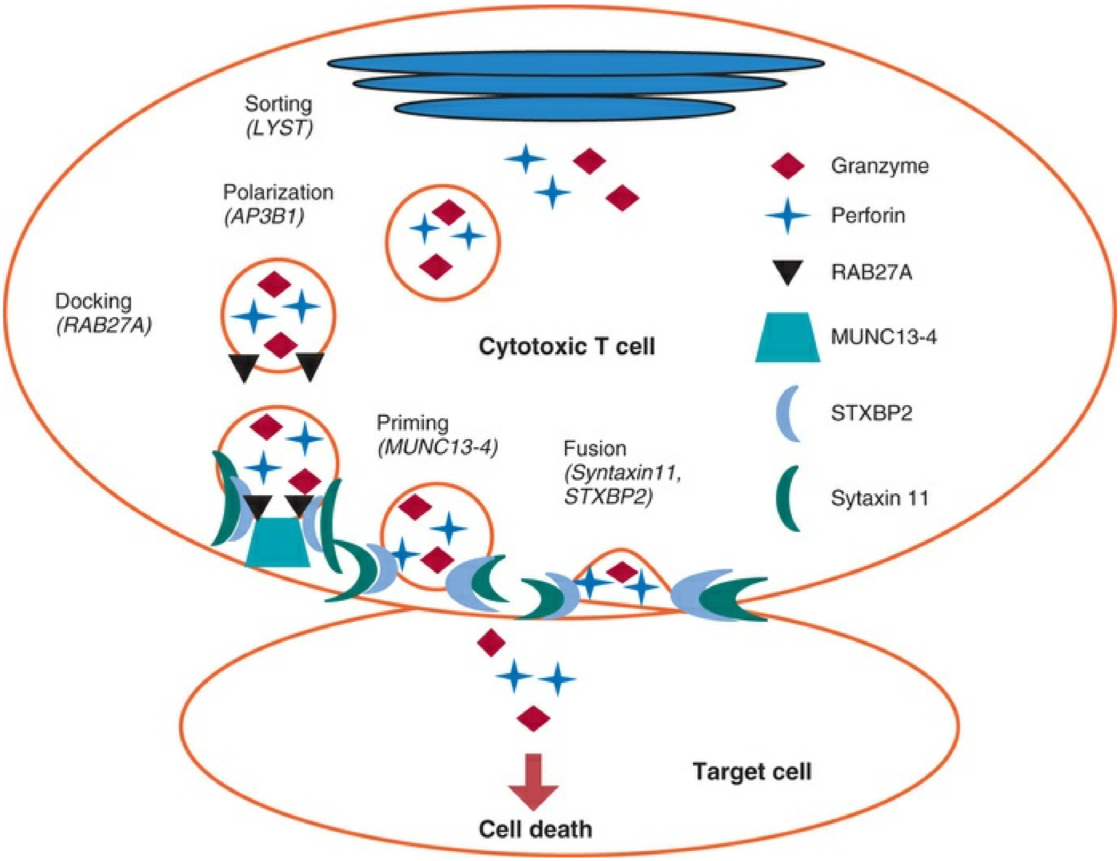

FIGURE 12.1 Steps in cytotoxic T-lymphocyte function leading to target cell death. Proteins involved with loading, moving, priming, and docking of the cytotoxic granules are shown in parenthesis, defects in the genes encoding these proteins leads to hemophagocytic lymphohistiocytosis (HLH). (Adapted from Filipovich AH, Chandrakasan S. Pathogenesis of hemophagocytic lymphohistiocytosis. Hematol Oncol Clin North Am 2015;29:895−902; and Madkaikar M, Shabrish S, Desai M, et al. Hemophagocytic lymphohistiocytosis: advances in pathophysiology, diagnosis, and treatment. J Pediatr 2013;163:1253−1259.)

Activated CD8$^+$ T lymphocytes and NK cells also release large amounts of interferon γ (IFNγ) and tumor necrosis factor-α, which potently activate macrophages and dendritic cells. A plausible scenario for primary HLH occurring in association with viral infection is that T lymphocytes and NK cells are activated by severe infection to secrete cytotoxins and cytokines, but cytotoxicity is ineffective in killing and eliminating the viral antigenic stimulus. This results in prolonged and persistent lymphocyte activation and cytokine secretion that, in turn, persistently activates macrophages and dendritic cells, leading them to become hemophagocytic[4,33,50] and to secrete additional proinflammatory cytokines. This combined lymphocyte and mononuclear phagocyte “cytokine storm” appears to be a common final pathway for HLH pathogenesis,[4,51] accounting for fever, hyperlipidemia, endothelial activation, coagulopathy, tissue infiltration of T lymphocytes and macrophages, CNS vasculitis and demyelination, marrow hyperplasia or aplasia, and multiorgan dysfunction and failure. In XLP1 disease, SAP deficiency selectively impairs recognition and killing of EBV-infected B lymphocytes by CD8$^+$ T lymphocytes and NK cells,[52,53] resulting in a high EBV viral load; other forms of activation and cytokine secretion by CD8+ T lymphocytes and NK cells are intact and driven by the persistent viral load. However, cases of HLH can occur in FHL without apparent associated infections, and these observations, along with studies in animals, suggest that perforin-dependent cell-mediated cytotoxicity, in addition to its antimicrobial role, also directly regulates lymphocyte activation and homeostasis.[3]

Secondary HLH most commonly occurs when overwhelming infection in an immunocompromised host triggers marked or prolonged T-lymphocyte and NK-cell activation and hypercytokinemia. Lymphocyte and mononuclear phagocyte-derived hypercytokinemia also is likely the cause of HLH in untreated leukemia and lymphoma, GvHD, or HLH after chemotherapy.

More enigmatic is the basis for HLH and hypercytokinemia after primary EBV infection in previously healthy children because only a minority of cases are accounted for by primary HLH genetic disorders.[54] In EBV-associated HLH and in EBV infection complicating primary HLH, there often are high levels of EBV genomes in circulating T lymphocytes,[55,56] but the importance of this T-lymphocyte tropism of EBV in HLH pathogenesis remains unclear.

Clinical and Radiologic Features

Primary and secondary HLH cannot be distinguished reliably on the basis of clinical, laboratory, or histopathologic features. Prolonged high fever, hepatosplenomegaly, and cytopenias generally are hallmarks of HLH. Rash, lymphadenopathy, respiratory tract and gastrointestinal symptoms, failure to thrive, and irritability are frequent (Table 12.2).[57–61] Clinical and laboratory abnormalities often peak at days 6 to 10 of illness, although there is substantial variability.[57]

TABLE 12.2

Clinical Manifestations of Hemophagocytic Lymphohistiocytosis

Symptoms	Present at Time of Diagnosis (%)
Fever	91–100
Hepatomegaly	89–97
Splenomegaly	61–98
Lymphadenopathy	17–52
Skin rash	6–65
Respiratory distress	33–88
Hypotension	85
Jaundice	72
Gastrointestinal	44
Neurologic	20–47

Adapted from references 57 to 61.

Systemic Manifestations

Fever, often prolonged, is present in all patients. HLH is an important diagnostic consideration in fever of unknown origin.[57] Organomegaly, often pronounced and progressive, is found in more than 90% of cases. A diffuse erythematous maculopapular or petechial rash may transiently appear with high fevers.[57] Respiratory tract symptoms are frequent and can vary from mild cough to acute respiratory distress syndrome requiring ventilatory support.[57] Cardiovascular collapse and renal failure can occur.[57] Lymphadenopathy, often prominent, is frequent (50% to 70% of patients).[57] Gastrointestinal symptoms, including vomiting, diarrhea, and abdominal pain, occur in about 40% of patients.

Central Nervous System Manifestations

Most HLH patients have neurologic symptoms or cerebrospinal fluid (CSF) abnormalities (mononuclear pleocytosis or elevated protein) at the time of diagnosis.[62] Rarely, hemophagocytosis of white blood cells of the CSF can be observed,[2] a finding that is specific for HLH. Neurologic symptoms can be the presenting feature, preceding clinical HLH by 2 or more years,[63] or can develop only later in the course.[2] Seizures, meningismus, and irritability are present commonly.[64] Cranial nerve palsies, ataxia, nystagmus, disturbances of gait and vision, hemiplegia or tetraplegia, delayed psychomotor development, and increased intracranial pressure have been reported. Frequent findings on magnetic resonance imaging or computed tomography include multiple nodular or ring-enhancing parenchymal lesions in the cerebrum and cerebellum, leptomeningeal enhancement, confluent parenchymal lesions with or without hemorrhage, and ventriculomegaly, which can be due to cerebral atrophy or hydrocephalus.[62,65] Demyelination can occur and mimic acute disseminated encephaloymyelitis.[66] Definitive diagnosis of CNS disease may require biopsy of the meninges and white matter.[67]

Hemophagocytic Lymphohistiocytosis in the Fetus and Neonate

HLH manifesting with liver failure[68,69] is more common in the fetus and neonate than in older children. Nonimmune hydrops fetalis[68,70] can be a presentation of HLH due to either FLH[21] or congenital infections, such as syphilis or rubella. Neonates and young infants with severe herpesvirus (herpes simplex virus, cytomegalovirus, or HHV-8) or enteroviral infections,[71] or bacterial or fungal sepsis[72] can develop secondary to HLH. This may be a more common complication of severe infection than in older, immunocompetent children, most likely because of developmental limitations in fetal and neonatal host defense mechanisms.[73]

Laboratory and Pathologic Findings

General

Characteristic laboratory abnormalities include pancytopenias, hypertriglyceridemia, hyperferritinemia, hyperbilirubinemia, transaminemia, and hypofibrinogenemia, but none is specific for HLH (Table 12.3).[1,57] Platelets are the most consistently depressed blood lineage, and thrombocytopenia may be a useful indicator of disease activity.[74] Approximately 80% to 90% of patients have two depressed blood cell lineages at presentation.[57] Neutrophils often are the last line to become depressed. Hypofibrinogenemia occurs in most patients and can occur in the absence of disseminated intravascular coagulation. Serum ferritin level is consistently elevated, and in approximately 90% of cases, this concentration exceeds 4000 μg/L. A ferritin level higher than 10,000 μg/L is 90% sensitive and 96% specific for HLH.[75] Hyponatremia and low serum protein and albumin concentrations are common.[57]

TABLE 12.3

Laboratory Findings in Hemophagocytic Lymphohistiocytosis

Laboratory Finding	Present at Time of Diagnosis (%)
Anemia	89–94
Thrombocytopenia (<100,000 platelets/mm^3)	82–100
Neutropenia (<1000 cells/mm^3)	58–100
Leukopenia	39–87
Hypertriglyceridemia	80–100
Hypofibrinogenemia	65–85
Elevated serum alanine aminotransferase level	33–92
Hyperbilirubinemia	33–74
Hyponatremia	79
Cerebrospinal fluid pleocytosis	52–91

Acta Paediatr Scand 1991;80:428–435; and Janka GE. Familial hemophagocytic lymphohistiocytosis. Eur J Pediatr 1983;140:221–230.

Clinical Immunology

In primary HLH due to FHL, Griscelli syndrome type 2, and Chédiak-Higashi syndrome, a functional defect in killing by CD8$^+$ T lymphocytes and NK cells occurs, and the circulating levels of CD4$^+$ and CD8$^+$ T lymphocytes and NK cells usually are normal or elevated.[33,76] NK-cell–mediated cytotoxicity is decreased only moderately or even is normal in some cases of primary HLH, including FHL,[77] whereas CD8$^+$ T-lymphocyte–mediated cytotoxicity is more uniformly impaired. In cases of secondary HLH, such as from severe EBV infection, the circulating number of NK cells often is reduced; most patients have transiently reduced NK-cell activity if blood is used as a source of NK cells for the assay.[9] The reason for this depression of circulating NK-cell numbers is unclear but may reflect NK-cell sequestration in the tissues away from the circulation. Circulating invariant NK T lymphocytes, which have features of NK cells and T lymphocytes, are absent in XLP1 disease[78] but are present in normal numbers in patients with XLP2 disease.[79] A decreased number of B lymphocytes is common in HLH, including from secondary causes,[80] which can pose challenges in diagnosing certain primary immunodeficiency disorders.[39] There are no consistent abnormalities of quantitative immunoglobulin levels.

Although cytokine assays are not routinely used diagnostically, HLH patients tend to have marked elevations of IFNγ, interleukin-10 (IL-10), and IL-18, and only moderately increased IL-6, whereas patients with bacterial septicemia often have markedly elevated levels of IL-6 and only moderate elevations of IL-10, IL-18, and IFNγ.[81]

Pathology

The classical histopathology is diffuse infiltration of the bone marrow, liver, spleen, lymph nodes, lungs, and brain with $CD8^+$ T lymphocytes and activated non-Langerhans (lacking expression of CD1a) histiocytes that are actively phagocytosing blood cells. Hepatic portal and sinusoidal infiltration with $CD8^+$ T lymphocytes expressing granzyme B, and with $CD68^+$ $CD1a^+$ histiocytes, is found characteristically in children with primary HLH. The degree of infiltration correlates with clinical disease severity.[82] Bile duct damage and endothelialitis with preservation of the hepatic parenchyma are frequent.[82] CNS tissue typically shows lymphohistiocytic infiltration of the parenchyma and perivascular space and hemophagocytosis in the leptomeninges, choroid plexus, or perivascular areas.[1] Importantly, the characteristic pathologic findings may not be present on an initial biopsy, and the demonstration of hemophagocytosis is not required to make the diagnosis (see later section, “Diagnosis”).

Evaluation for Infectious Diseases

Initial evaluations should include bacterial and fungal cultures of blood, urine, and in most cases, CSF; throat and rectal swabs for viral culture; and a chest radiograph. Serologic evaluation for viruses and fungi should be pursued, although these may not be sensitive in immunocompromised hosts. Polymerase chain reaction −based nucleic acid tests for EBV, CMV, parvovirus B19, HHV-6, and HIV infection should be performed; an elevated viral load supports the diagnosis of a poorly controlled viral infection. Specific epidemiologic factors, such as exposure to tuberculosis, travel, and animals, should guide further testing given the broad range of pathogens associated with HLH.

Diagnosis and Differential Diagnosis

The diagnosis requires either confirmation of primary HLH (e.g., by genomic DNA sequencing or flow cytometry) *or* presence of more than 5 of the 8 clinical criteria presented in Box 12.1. Hemophagocytosis may not be evident in bone marrow biopsies obtained early in the disease, and repeat bone marrow aspirates or analysis of other tissues may be required.[1,33] The diagnosis is supported by CSF mononuclear cell pleocytosis and elevated protein or a liver biopsy showing chronic persistent hepatitis. Other findings that are suggestive include meningitis or cerebritis, lymphadenopathy, elevation of serum hepatic enzymes, jaundice, edema, hypoproteinemia, hyponatremia, increased serum level of very low density lipoproteins, and decreased level of high-density lipoproteins.[1]

Box 12.1

Diagnostic Criteria for Hemophagocytic Lymphohistiocytosis (HLH)

The diagnosis of HLH can be established by either a molecular diagnosis consistent with HLH *or* fulfillment of ≥5 of 8 diagnostic criteria:

Original Diagnostic Criteria

Clinical

1. Fever

2. Splenomegaly

Laboratory

3. Cytopenia (≥2 cell lineages in the peripheral blood)

- Hemoglobin <9 g/dL (<10 g/dL if <4 weeks of onset)
- Platelets <100,000/mm^3
- Neutrophils <1000/mm^3

4. Hypertriglyceridemia and/or hypofibrinogenemia

- Fasting triglycerides ≥265 mg/dL
- Fibrinogen ≤150 mg/dL

Histopathologic

5. Hemophagocytosis in bone marrow, spleen, or lymph nodes without evidence of malignancy

New Diagnostic Criteria

Laboratory

6. Low or absent natural killer cell activity

7. Ferritin >500 μg/L

8. Soluble interleukin-2 receptor α chain (CD25) ≥2400 U/mL

Adapted from Henter JI, Samuelsson-Horne A, Aricò M, et al. Treatment of hemophagocytic lymphohistiocytosis with HLH-94 immunochemotherapy and bone marrow transplantation. Blood 2002;100:2367–2373 and HLH-2004 protocol: www.histio.org/society/protocols/trails-protocols.html.

NK-cell cytotoxicity, in which peripheral blood mononuclear cells containing NK cells are incubated with chromium-labeled K562 erytholeukemia target cells, should be evaluated in inflammatory conditions. NK-cell cytotoxicity is markedly decreased or undetectable in most cases of primary or secondary HLH.[9,76,80] Circulating NK cells ($CD56^+/CD16^+/CD3^-$ lymphocytes) usually are present in normal or elevated numbers but functionally are defective in patients with primary HLH.[83] In secondary HLH, particularly in association with EBV infection, the numbers of NK cells often are depressed markedly, accounting for impaired cytotoxicity[9]; activity may return to normal with the recovery of NK-cell numbers. Normal or borderline low NK-cell activity can occur in certain forms of FHL and some cases of XLP disease. Flow cytometric evaluation for cytotoxic granule release based on surface staining of lymphocytes for the CD107a/b proteins[13] may be particularly useful in classifying FHL cases.[3,13]

Clinical flow cytometry assays are available for the determination of T-lymphocyte and NK-cell intracellular perforin, SAP, and XIAP, which are encoded by genes that are mutated in FHL2, XLP1 disease, and XLP2 disease, respectively.[13,84] Genomic DNA sequencing is important in the initial evaluation for primary HLH because normal flow cytometric protein assays do not exclude the diagnosis (see http://www.ncbi.nlm.nih.gov/sites/GeneTests; Fig. 12.2).[49,85] Clinical FHL can occur in the absence of any of the known genetic causes of primary HLH, suggesting that other genetic etiologies remain to be defined. Thus, without a previous family history or genetic confirmation, the diagnosis of primary HLH is provisional, and it is essential to exclude malignancy and autoimmune disease as precipitants.

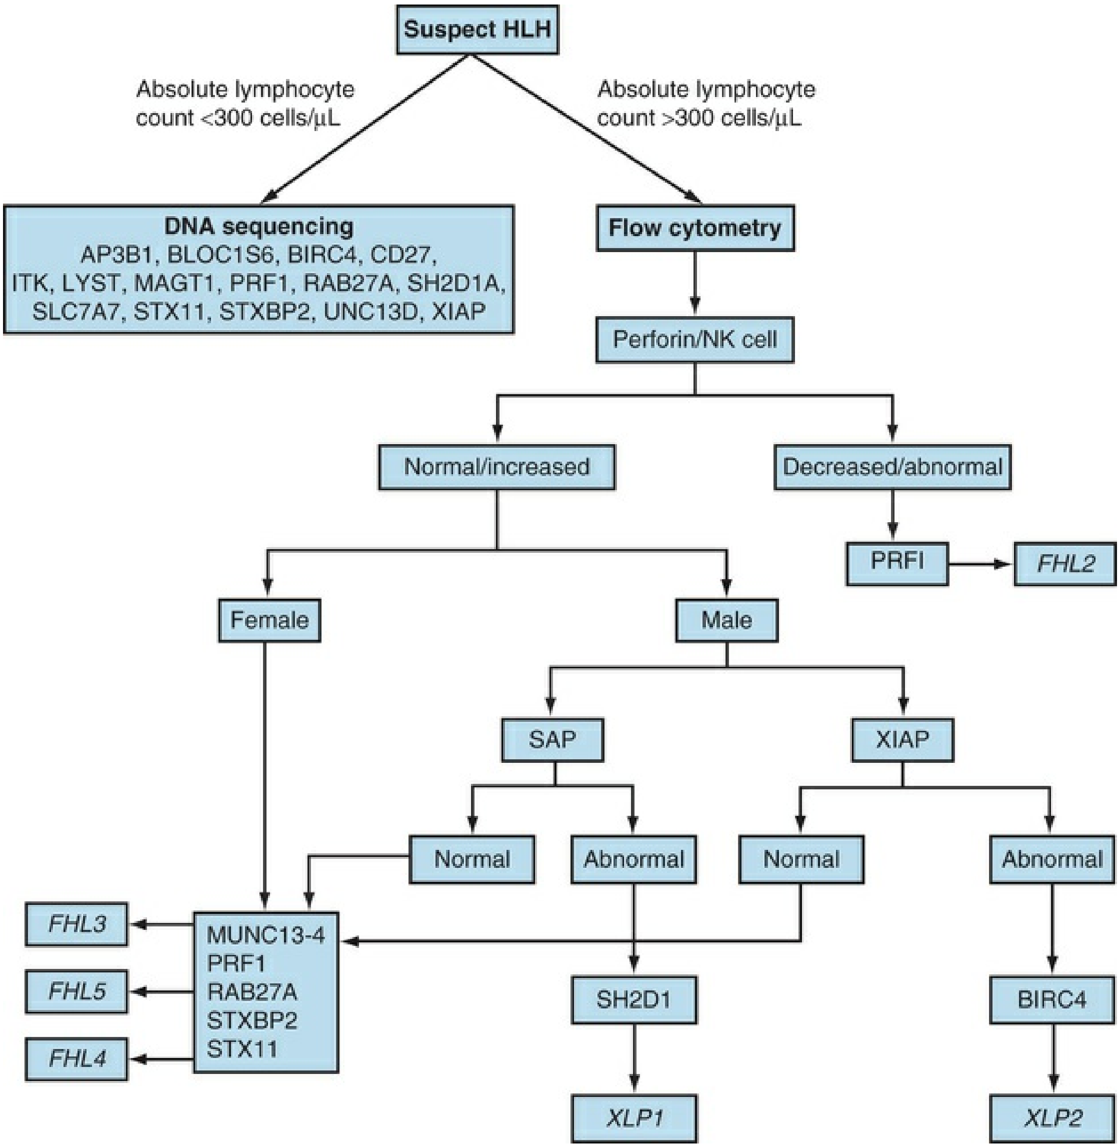

FIGURE 12.2 Diagnostic evaluation for suspected hemophagocytic lymphohistiocytosis (HLH) including genetic and immune testing. (Adapted from Filipovich AH, Chandrakasan S. Pathogenesis of hemophagocytic lymphohistiocytosis. Hematol Oncol Clin North Am 2015;29:895−902; and Madkaikar M, Shabrish S, Desai M. Current updates on classification, diagnosis and treatment of hemophagocytic lymphohistiocytosis [HLH]. Indian J Pediatr 2016;83:434−443.)

The nonspecific nature of the most prominent features of HLH (i.e., fever, hepatosplenomegaly, and cytopenias) leads to a broad differential diagnosis, which includes leukemia, lymphoma, aplastic anemia, myelodysplasia, and Langerhans cell histiocytosis. In the fetus and neonate, other etiologies of liver failure, hepatitis, and hydrops fetalis should be considered. Differential diagnosis of neurologic disease includes autoimmune and acute disseminated encephalomyelitis, other CNS demyelinating disease,[66] and vasculitis.

Treatment

Advances have been made in the treatment of HLH over the past two decades due in large part to the guidelines put forth by the Histiocyte Society in 1994 and 2004.[1,74] HLH previously was a fatal disease, but the survival of HLH patients has improved to more than 60% with the use of chemoimmunotherapy combined with hematopoietic stem cell transplantation (HSCT). Aggressive supportive care with transfusions, antibiotics, and nutrition typically is indicated. An integrated team approach of experts in hematology-oncology, immunology, infectious diseases,[57] critical care, neurology, and nephrology is ideal. Close monitoring for secondary bacterial and fungal infections and for adequate hemostasis is important because infections and bleeding are important causes of HLH mortality.[86]

Immunosuppression and Chemotherapy

First-line treatment is focused on suppressing the hyperimmune state. Aggressive immunotherapy of primary HLH, before definitive genetic diagnosis, which may take months, may be necessary because a delay can have adverse consequences.[5] The natural course of untreated primary HLH is progressive multiorgan failure and CNS disease, with a mean survival of only 2 months.[74] Secondary HLH also can have a high mortality, especially if EBV induced,[33] although some cases can resolve spontaneously without therapy.[87] The type of treatment for children with HLH is determined by disease severity, age at onset, and history of familial disease.[1,88] The updated 2004 HLH protocol serves as a treatment guide for cases of primary HLH and severe, persistent, or recurrent secondary HLH, particularly EBV-associated HLH.[1,5,89] The therapeutic goals are to induce remission and to bridge to HSCT when indicated. For patients with primary HLH or severe secondary disease, especially EBV-associated HLH, treatment includes etoposide, corticosteroids, and cyclosporine for 8 weeks. For all cases of primary HLH and for secondary HLH that does not respond to initial therapy, intrathecal methotrexate may be used. If neurologic symptoms persist, recur, or progress, intrathecal glucocorticoid therapy may be useful. These agents help control HLH by inducing apoptosis of lymphocytes and histiocytes (mainly an effect of etoposide) and by inhibiting cytokine and chemokine production (mainly an effect of glucocorticoids and cyclosporine). Relapses are common as treatment is reduced, especially in FHL, and may require reescalation of therapy.[1] Etoposide usually is not used in cases of secondary HLH complicating HIV infection or iatrogenic immunosuppression. Etoposide therapy often results in prolonged neutropenia and is associated with a later risk for acute myeloid leukemia. FHL has been treated with etoposide-free regimens, such as the combination of antithymocyte globulin, glucocorticoids, cyclosporine, and intrathecal methotrexate.[90] Severity of HLH may dictate individualized treatment protocols, and for some less severe cases, corticosteroids may be sufficient, but disease progression and relapse must be monitored very carefully.

For EBV-associated HLH, which can have a highly variable course,[87] relatively conservative therapies, such as glucocorticoids and cyclosporine, with or without immune globulin intravenous, can be considered, reserving etoposide for nonresponsive cases.[91] In EBV-associated HLH and primary HLH in XLP disease, rituximab (CD20 monoclonal antibody) has been used.[92,93]

Overall, complete response to initial HLH treatment is only seen in 50% to 75% of individuals, with inactive disease at 8 weeks correlating with survival.[94]

Hematopoietic Stem Cell Transplantation

Patients with primary HLH ultimately require allogeneic HSCT for cure.[1] Reduced intensity nonmyeloablative conditioning regimens have had particularly favorable results.[95] Patients with primary HLH who have early relapse of HLH or persistent CNS involvement may benefit from early HSCT.[96] HSCT also has been used for EBV-associated HLH, particularly for those with recurrent disease.[97] The timing of the transplantation is important; patients with active HLH at transplantation tend to have worse outcomes compared with patients with inactive disease because active disease increases graft failure.[94]

Prognosis

If untreated, primary HLH, particularly FHL, is almost uniformly fatal.[1] Increased survival is associated with prompt response to initial therapy and with older age at presentation.[98] Secondary HLH can be a self-limited process, with recovery after only supportive measures. Longterm remission is uncommon in patients with CNS disease and in those older than 30 years[99]; early aggressive therapy for severe or recurrent cases appears to be beneficial.[100] A soluble CD25 serum level of 10,000 U/mL[101] or greater also has been associated with mortality.[51] HLH patients who have a 96% or more drop in serum ferritin with therapy have a reduced risk for mortality.[102]

Macrophage Activation Syndrome

Systemic-onset juvenile idiopathic arthritis (sJIA) is a frequent cause of MAS in childhood,[103] and the presence of defective NK-cell function due to NK-cell lymphopenia is similar to that associated with other causes of secondary HLH.[103,104] Clinical and laboratory findings of MAS include persistent fever, hepatosplenomegaly, neurologic abnormalities, marked cytopenias, and coagulopathy.[9] Because some diagnostic criteria for HLH also can occur with exacerbations of sJIA (lymphadenopathy, splenomegaly, and hyperferritinemia), a marked elevation of serum CD25 and CD163 levels[105] can help make the diagnosis of MAS in this context. In an attempt to increase the specificity and sensitivity of diagnostic criteria, a new set of clinical and laboratory criteria have been put forth that improve on the HLH-2004 protocol in diagnosing MAS.[106] This study showed low sensitivity and specificity of clinical criteria but strong predictions for the presence of three or more laboratory studies including, among others, platelets count ($\leq$211,000/mm^3), lactate dehydrogenase level (>882 U/L), total protein ($\leq$6.3 g/dL), albumin ($\leq$2.9 g/dL), aspartate transaminase (>59.7 U/L), fibrinogen ($\leq$180 mg/dL), and ferritin (>400 μg/L).[106] MAS can be managed in most cases using immunosuppression without chemotherapy. The optimal regimen remains controversial and may depend on the underlying disorder; for example, IL-1 and IL-6 appear to play a central role in sJIA inflammation and MAS,[107] which may account for some patients responding to inhibitors of IL-1 (e.g., anakinra) or IL-6.[107]

Mucocutaneous Symptom Complexes

Sarah S. Long, Ishminder Kaur

Generally, in differentiating between bacterial and viral causes of febrile illnesses in children, the more mucous membranes involved in the patient's illness (e.g., conjunctiva, throat, respiratory, gastrointestinal tract), the more likely the cause is viral. When multiple mucous membranes are involved and an exanthem (i.e., mucocutaneous complex) is present, a self-limited viral cause is likely, but other important diagnoses must be considered. These commonly include inflammatory or immunologically mediated conditions, such as Kawasaki disease (KD), Stevens-Johnson syndrome (SJS) or toxic epidermal necrolysis (TEN), drug hypersensitivity, and bacterial toxin-mediated diseases, including staphylococcal and streptococcal toxic shock, streptococcal scarlatiniform disorders, and staphylococcal exfoliative toxin syndromes or staphylococcal scalded-skin syndrome. A best, if not the definitive, diagnosis can be deduced through careful assessment of (1) the dominant features of the illness; (2) prodromal events and exposures; (3) specific characteristics of the exanthem and abnormality at each affected mucous membrane; and (4) the cadence of the developing constellation. Laboratory features are of secondary importance, heightening or diminishing the fitness of the clinical assessment.

Table 13.1 shows useful differentiating features of commonly considered causes of mucocutaneous symptom complexes. Features distinguishing streptococcal toxic shock due to streptococcal pyrogenic exotoxin (SPE) A or B from staphylococcal toxic shock associated with toxic shock syndrome toxin-1 (TSST-1) are shown in Table 13.2 and are described in the discussion where pertinent. SJS and TEN are considered ends of the same disease spectrum, whereas erythema multiforme (EM) is a separate entity distinct from SJS and TEN. EM is characterized by target lesions, whereas the skin lesions of SJS and TEN are widespread and consist of blistering on erythematous or purpuric macules. Table 13.3 shows differentiating features of EM, SJS, and TEN.[1,2]

TABLE 13.1

Differentiating Among Causes of Mucocutaneous Symptom Complexes

	Kawasaki Disease	Toxic Shock[a]	Staphylococcal Exfoliative Toxin Syndromes	Streptococcal Scarlatina	Steve Synd
CLINICAL FEATURES					
Fever	+++	+++	+	+	++
	≥5 days	<2 days	2–3 days	2–3 days	5 day
Conjunctiva	+++	+++	++	−	++
	Bilateral hyperemia (bulbar > palpebral); anterior uveitis	Bilateral hyperemia (bulbar > palpebral)	Unilateral or bilateral purulent conjunctivitis (palpebral > bulbar); or normal	Normal	Bilate conju chem kerat pano
Lips	+++	++	−	−	+++
	Erythema, fissures	Erythema	Normal or desquamation	Normal, with circumoral pallor	Eryth edem denu bleed escha
Oropharynx	+++	++	−	++	++
	Mucosal erythema; strawberry tongue	Mucosal erythema; strawberry tongue	Normal, or mucosal erythema	Tonsillar erythema, exudate; palatal petechiae; strawberry tongue	Pann eryth confl ulcer denu pseu
Exanthem	+++	++	+++	+++	+++
	Polymorphous, nonvesicular,	Erythroderma	Indurative or papular	Papular erythroderma	Eryth multi

	vasoactive and changing; morbilliform, symmetric; exaggerated or solely in groin		erythroderma; tender; Nikolsky sign and desquamation during acute phase	(sandpaper); Pastia sign	polyr fixed,
Extremities	++	++	–	–	–
	Symmetric, indurative edema distally; painful erythema, palms and soles; stocking-glove distribution; occasional digital cyanosis	Symmetric distally; erythema on palms and soles	Normal, or edema contiguous with exanthem	Normal	Norm edem conti exant
Other	+++	+++	+	+	++
	Unremitting crankiness; cervical lymphadenopathy; arthralgia, arthritis; meningismus, cranial nerve palsy; abdominal pain, distention, tenderness; hydropic gallbladder	Profuse prodromal diarrhea; dizziness, headache, confusion; hypotension, shock; hydropic gallbladder	Infected tissue site	Sore throat, odynophagia; cervical lymphadenitis; malaise, vomiting	Mala arthr ureth ulcer symp abdo diarr
Predominant feature(s)	+++	+++	+++	++	+++
	Persistent fever and unremitting crankiness	Fever and prostration	Desquamating skin lesions	Exanthem and sore throat	Edem bloo oral pseu
Convalescent clinical features	+++	+++	+++	+++	++
	Desquamation periungually to palms and soles (full thickness); minimal desquamation elsewhere; hair loss, nail abnormalities; coronary artery aneurysms and thrombosis	Desquamation hands and feet (full thickness); mild desquamation elsewhere; hair loss, nail abnormalities	Desquamation extensive during acute and convalescent periods	Desquamation hands and feet (full thickness); desquamation extensive elsewhere	Desq sites lips, recur seriou ophth seque
LABORATORY FEATURES					
	Elevated peripheral neutrophils, platelets, sedimentation rate; anemia, hypoalbuminemia; sterile pyuria; ± electrocardiographic or echocardiographic abnormalities	Thrombocytopenia, left shift of neutrophils; coagulopathy; hyponatremia; multiorgan dysfunction related to hypoperfusion; acute respiratory distress syndrome	Left shift of neutrophils; hypovolemia in young infant; bacteremia or septicemia related to infected site	Elevated peripheral neutrophils	Eleva perip neutr sedin rate

DIAGNOSIS					
	Clinical, with exclusion of others and supportive laboratory findings; response to IGIV; ectasia, aneurysm, or thrombosis of coronary arteries	TSST-1 producing *Staphylococcus aureus* recovered (from mucosa or infected site); response to aggressive fluid support, antibiotic	Exfoliative toxin (ETA and ETB) producing *S. aureus* recovered (usually not from the skin lesions but from the primary site of infection[19]); response to antibiotic	Erythrogenic toxin-producing *Streptococcus pyogenes* recovered (usually from throat); response to antibiotic	Clini impr recur
TREATMENT					
	IGIV 2 g/kg Aspirin (high dose followed by low dose)	Crystalloid, colloid, then pressor agents; penicillinase-resistant antibiotic (or vancomycin) plus clindamycin; IGIV not proved (see text)	Penicillinase-resistant antibiotic (consider adding vancomycin or clindamycin); supportive fluids	Penicillin	Supp disco inciti cortic IGIV

[a] Features of staphylococcal toxic shock (i.e., related to TSST-1); see text and Table 13.2 for differences in streptococcal toxic shock.

IgE, immunoglobulin E; IGIV, immune globulin intravenous; TSST, toxic shock syndrome toxin; +++, prominent, expected finding; ++, frequent finding; +, variable finding; −, not present.

TABLE 13.2

Comparative Features of Toxic Shock Syndrome[a]

Feature	Staphylococcal Toxic Shock	Streptococcal Toxic Shock
Primary toxin	TSST-1	SPEA, B
Prodrome	Vomiting, diarrhea	Flu-like illness
Duration prodrome	Hours	Hours to days
Severity prodrome	+++	+
Focal infection	+	++
Extreme pain and hyperesthesia at focal site	−	+++
Rash	Erythroderma	Scarlatina or none
Shock	Predictable	Unpredictable, related to clotting
	Treatable	Sometimes untreatable
Multiorgan failure	Predictable, related to blood pressure	Unpredictable
	Treatable	Sometimes untreatable
Positive blood culture	−	++
Coagulopathy	+	+++
Complicated hospitalization	+	+++
Gangrene	±	+++

Mortality	+	++

[a]Differences represent general comparisons rather than clinical findings or outcomes in individual patients.

SPE, streptococcal pyrogenic exotoxin; TSST, toxic shock syndrome toxin; ±, not an expected occurrence; +, occurs, but infrequently; ++, occurs with some frequency; +++, occurs commonly; −, does not occur.

TABLE 13.3

Differentiating Features of Erythema Multiforme (EM) Minor, EM Major, Stevens–Johnson Syndrome (SJS), and Toxic Epidermal Necrolysis (TEN)

	Skin Lesions	Distribution of Skin Lesions	Mucosal Involvement	Detachment Skin (% TBSA)	Systemic Symptoms	Pathology	Pre Fac
EM minor	Typical target lesions[a] ± atypical papular target lesions[b]	Extremities and face > trunk	Absent or mild if present	None	Absent	Nonspecific, including apoptotic keratinocytes and dermal inflammation	Her sim viru Oth infe age
EM major	Similar to EM minor with occasional bullous lesions	Similar to EM minor	Present	Occasional, minimal	Present	Similar to EM minor	Sim EM
SJS	Lesions are widespread with blistering on erythematous or purpuric macules; atypical macular target lesions[c]	Trunk and face > extremities	Present	Confluence of blisters results in epidermal detachment of <10% TBSA[d]	Present	Apoptotic keratinocytes; subepidermal cleavage; keratinocyte necrosis; dermal inflammation	Dru occ infe age
TEN	Similar to SJS	Similar to SJS	Present	Confluence of blisters results in epidermal detachment of >30% TBSA[d]	Present	Similar to SJS	Sim SJS

[a]Typical target lesions are <3 cm with regular round shape, well-defined borders, and 3 distinct zones.

[b]Atypical papular target lesions are round, edematous, and palpable with 2 zones or indistinct border.

[c]Atypical macular lesions are nonpalpable targets (with exception of central blister) with round shape and 2 zones or indistinct border.

[d]Overlap SJS-TEN: confluent blisters result in detachment of 10% to <30% TBSA.

TBSA, total body surface area.

Modified from Auquier-Dunant A, Mockenhaupt M, Naldi L, et al; SCAR Study Group. Severe cutaneous adverse reactions. Correlations between clinical patterns and causes of erythema multiforme majus, Stevens-Johnson syndrome, and toxic epidermal necrolysis: results of an international prospective study. Arch Dermatol. 2002;138:1019−1024; and French LE, Prins C. Erythema multiforme, Stevens-Johnson syndrome and toxic epidermal necrolysis. In: Bolognia JL, Jorizzo JL, Schaffer JV (eds). Dermatology, 3rd ed. St. Louis, Elsevier, 2012:319−333.

Less common conditions share certain clinical features of the mucocutaneous syndromes shown in Table 13.1 but usually can be distinguished on the basis of circumstances of occurrence, such as recurrences and periodicity of febrile episodes in periodic fever with aphthous stomatitis, pharyngitis, and adenitis (the PFAPA syndrome)[3] and chronicity and additional findings in Behçet disease.[4] Although the ulcerative gingivitis and pseudomembrane of mucositis associated with neutropenia and anticancer chemotherapy[5] can be indistinguishable from the confluent denuding ulcers of SJS, the clinical setting of the former, as well as the absence of conjunctivitis and rash, distinguishes mucositis from SJS. Most commonly, SJS is associated with antibiotics or anticonvulsant drugs or with *Mycoplasma* infection.[6–8] Medications strongly associated with SJS and TEN include sulfonamides, phenobarbital, lamotrigine, and carbamazepine. Reports of cases and case series, however, implicate a myriad of medications, including acetaminophen and ibuprofen.[9] Paraneoplastic vasculitis complicating myeloproliferative disorders can manifest with urticaria, EM, or palpable purpura. This diagnosis is suspected because of the associated malignancy and is confirmed by skin biopsy.[10]

Rocky Mountain spotted fever (RMSF), an infective vasculitis caused by *Rickettsia rickettsii,* shares many features of other mucocutaneous syndromes (i.e., high fever, progressive serious illness, conjunctival hyperemia and suffusion, peripheral edema despite hypovolemia, and hyponatremia), but the presence of unremitting headache, peripheral petechial rash, season (illness onset during summer), and exposure to ticks usually sets RMSF apart.[11] Ehrlichiosis and anaplasmosis occur in a similar setting; leukopenia may be a clue.[12] Empiric treatment for RMSF or ehrlichiosis with doxycycline regardless of age sometimes is required because the diagnoses cannot be reasonably or quickly excluded. Leptospirosis is indistinguishable from RMSF, except possibly for a biphasic illness and disproportionate kidney or liver involvement in leptospirosis.[13] Drug hypersensitivity reactions can manifest a variety of mucocutaneous abnormalities, including immediate immunoglobulin E (IgE)-mediated rashes and delayed reactions, SJS, TEN, drug rash with eosinophilia and systemic symptoms (DRESS), and acute generalized exanthematous pustulosis (AGEP).[14–16] DRESS is characterized by diverse cutaneous eruptions (often evolving into indurated edematous erythroderma), with or without mucosal involvement, and systemic involvement that can include hematologic, hepatic, renal, pulmonary, cardiac, neurologic, gastrointestinal, or endocrine abnormalities.[17] The exanthem of AGEP is generalized with multiple sterile, nonfollicular pustules accentuated in the skinfolds, and it typically spares mucous membranes.[15]

For the previously healthy child or adolescent who comes to medical attention in shock, the following must be considered: septic shock from unrecognized ruptured appendix, urosepsis, invasive meningococcal or pneumococcal infection (especially if petechiae, purpura, or purpura fulminans is present), and septic or toxic shock from disseminated staphylococcal and group A streptococcal infection. *Streptococcus pneumoniae* and group B streptococcus also can cause toxic shock–like manifestations, which probably are related to cytokine stimulation.[18]

Specific Distinguishing Characteristics

Fever and Prodrome

The patient's duration of fever and sequence of clinical events provide useful clues to diagnosis. Although children with KD and bacterial toxin-mediated syndromes ultimately share many mucocutaneous features, the cadence of the prodrome is distinct. The child with staphylococcal toxic shock usually has profuse diarrhea and severe prostration within hours of onset of fever.[19,20] KD begins with fever and crankiness, sometimes with unilateral cervical lymphadenitis, the concern for diagnosis arising only when fever and crankiness persist and the symptom complex evolves rather than abates.[21,22] An important exception occurs in less than 10% of children with KD, who have rapidly progressive disease with hypotension requiring admission to an intensive care unit and who frequently are misdiagnosed as having septic or toxic shock.[23] The young child with staphylococcal exfoliative toxin syndrome can manifest rapidly progressive and dramatic skin manifestations, before or without severe systemic illness.[24,25]

Enteroviruses and respiratory viruses that cause mucocutaneous findings evolve over 3 to 5 days; nasal symptoms, rhinorrhea, hoarseness, or cough is present in more than 75% of cases, distinguishing these viral infections from KD. High fever (≥39.2°C) or persistent fever (≥5 days) does not eliminate viral etiology because viruses commonly considered in such patients (adenovirus, influenza A and B viruses) typically cause high fever and at least one third of affected children have fever beyond 5 days.[26–28]

Conjunctiva

To ascribe conjunctival findings accurately, the examiner must pay particular attention to (1) presence of inflammation and exudate versus erythema alone; (2) relative involvement of bulbar versus palpebral and tarsal sites; (3) presence or absence of photophobia, pain on movement, and itching; and (4) presence of uveitis, destructive keratitis, and panophthalmitis versus superficial inflammation.

Ocular manifestations of many infectious, inflammatory, allergic, and toxin-mediated conditions begin with bilateral conjunctival erythema.[29] The earliest ocular findings of KD, measles, SJS, RMSF, and leptospirosis, for example, cannot be distinguished. However, in KD, toxic shock syndromes, leptospirosis, and many cases of RMSF, nonedematous, nonexudative erythema of bulbar conjunctivae bilaterally is the complete evolution. In sharp contrast, adenoviral conjunctivitis is unilateral in 65% of cases, is predominantly palpebral (frequently with follicular lymphoid hyperplasia), and is associated with keratitis, purulent exudate, and photophobia in approximately one half of cases and with concurrent pharyngitis in 55%.[30] Conjunctivitis due to other viruses usually is bilateral, palpebral, and exudative.

Bacterial conjunctivitis (especially that due to nontypable *Haemophilus influenzae, S. pneumoniae,* or *Staphylococcus aureus*) is purulent, and bilateral usually; other mucocutaneous symptoms are not present (except with exfoliative toxin-producing *S. aureus* infection). Concurrent acute otitis media is common when nontypable *H. influenzae* is causative.[31] Orbital and periorbital cellulitis manifest predominantly with eyelid edema, erythema, and chemosis. Ocular itching, tearing, and photophobia accompany the "red eye" of allergic disorders; papillary hypertrophy of the palpebral conjunctivae is characteristic.

The findings of light sensitivity, ocular pain, and decreased vision suggest uveitis, which is characteristic of juvenile idiopathic arthritis (JIA) and Behçet disease. Such forms of JIA generally are not associated with fever and rash. Anterior uveitis is common in KD, being present in 83% of children examined in the first week and in 66% examined after the first week in one study.[32] Unlike other causes of uveitis, the inflammation in KD is mild and transient and is associated with minimal photophobia or pain. SJS frequently is associated with severe anterior-segment involvement, with exudative conjunctival discharge and sloughing of epithelium as well as pseudomembrane formation, and has the potential to cause subsequent severe corneal and eyelid scarring.[33] Anterior uveal inflammation can occur with measles and leptospirosis but is not expected with other mucocutaneous syndromes (e.g., streptococcal or staphylococcal toxin-mediated diseases, enteroviral or adenoviral infection, rickettsial diseases). Ophthalmologic evaluation with slit-lamp examination is valuable in children with evolving conjunctival findings and a mucocutaneous syndrome to uncover intraocular disease, and to aid in the diagnosis and sometimes sight-sparing management of SJS.

Lips

In infants, the lips (and frequently the ears) are brightly colored when fever is high, returning to normal with even transient defervescence. The lips infrequently are involved in mucocutaneous syndromes due to viruses, except during primary herpes simplex stomatitis, when diagnosis is apparent. Measles and influenza may be other exceptions, in which lips can be red, edematous, and cracked after several days of high fever.[34] The lips are noticeably red and occasionally are cracked and fissured in KD and toxic shock. The swollen, denuded, bleeding lips with black eschar of SJS (Fig. 13.1) are pathognomonic—involving the mucocutaneous junctions of lips, conjunctivae, urethra, and anus.

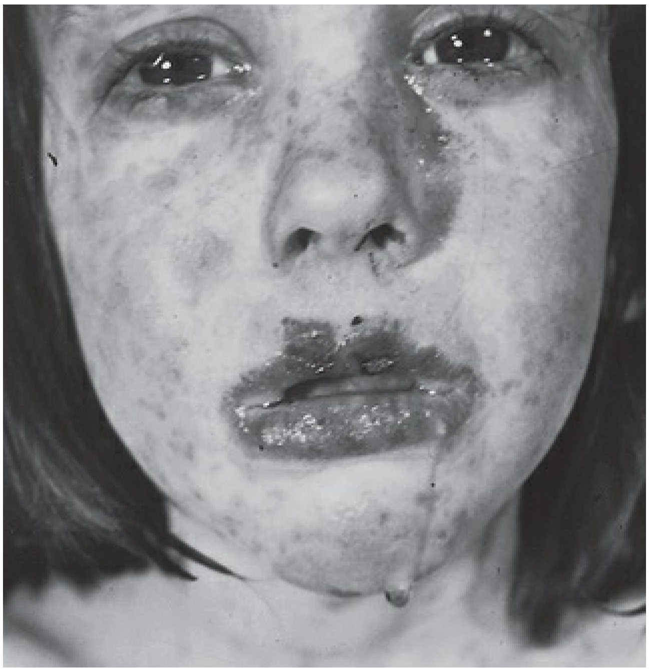

FIGURE 13.1 Ten-year-old girl with Stevens-Johnson syndrome and characteristic denudation of mucocutaneous junctions of the lips.

Oropharynx

Examination is performed to detect (1) diffuse erythema, sometimes with uvulitis (KD and toxic shock); (2) hypertrophied or dilated papillae on the tongue to give the appearance of a strawberry tongue (KD, toxic shock, streptococcal scarlatina); (3) confluent buccal and gingival ulceration with pseudomembrane formation (SJS and mucositis of neutropenia and antineoplastic drug therapy); (4) palatal petechiae (*Streptococcus pyogenes* and Epstein-Barr virus); (5) discrete ulcers (enteroviruses, herpes simplex virus); (6) Koplik spots (rubeola); and (7) exudative enanthem (*S. pyogenes,* respiratory tract viruses, Epstein-Barr virus). The singular (or few) deep, large ulcerative lesions of aphthous stomatitis and Behçet disease characteristically are found on the buccal or lingual mucosa or the lateral tongue.

Exanthem

The exact characteristics, distribution, pattern of evolution, and timing and manner of resolution of exanthematous lesions have differentiating features. Vesicular skin eruptions are almost unique to herpesviruses and enteroviruses.[35] Bullae are the typical initial lesions of staphylococcal exfoliative toxin syndrome, as is sloughing of sheets of epidermis with gentle tangential pressure or minor trauma on erythematous skin—Nikolsky sign. Nikolsky sign also can be elicited in SJS and TEN and in autoimmune bullous skin diseases, such as bullous pemphigoid.[15,36] Localized hemorrhagic bullae can form in the skin overlying necrotizing cellulitis, myositis, or fasciitis, especially due to toxin-producing *S. pyogenes.*[37] Blistering erythema, the hallmark of SJS, occurs first in localized areas (usually on the head and trunk), evolves to confluence over days, then appears and subsequently evolves at other sites (see Table 13.3; see also Chapter 70). The histology of skin lesion shows full-thickness epidermal necrosis with subepidermal cleavage in SJS and TEN compared with intraepidermal cleavage without keratinocyte necrosis in staphylococcal exfoliative toxin syndrome.[1,2]

Vesicular, bullous, or petechial lesions are distinctly rare in KD. The rash of KD is polymorphous (patchy macular, maculopapular, infrequently papular) and is indistinguishable in individual cases from the exanthem of viral infection, drug or food allergy, SJS, or toxin-mediated disease; however, characteristically, the rash in KD is fiery red, morbilliform (confluent), symmetric (when involving hands, feet, knees, and elbows), and changeable from hour to hour, rather than fixed as in viral infection or SJS. Although urticarial and EM-like lesions can occur in KD, they are not fixed. Rashes in KD characteristically spare the head, whereas exanthems in many viral infections, SJS, and staphylococcal toxin diseases commonly begin on, or involve, the face. Exaggeration or confinement of exanthem at the groin is characteristic of KD[38] but also can occur in streptococcal scarlatiniform eruptions, staphylococcal exfoliative toxin syndrome, influenza,[34] and bacterial cellulitis in the neonate.

Erythema, induration of the scrotum, and pain in the testicles can occur in KD and RMSF; a hydrocele can appear acutely.[39]

Viral exanthems are not painful or tender. The skin of children with diffuse staphylococcal exfoliative toxin syndrome, however, is erythematous and edematous, sometimes has a sandpaper quality, and usually is painful and tender.[40] In KD, specific sites of exanthem are not painful except on the hands and feet, where edema frequently leads to refusal to bear weight. If the patient complains of exquisite pain, sometimes with hyperesthesia or hypoesthesia out of proportion to local findings, toxin-producing streptococci (usually β-hemolytic group A streptococci, but also groups B, C, and G on occasion, and *S. pneumoniae,* the last especially in individuals with connective tissue diseases)[41] and necrotizing *S. aureus* infections must be considered.[37,42]

Epidemiologic features, such as season, exposure, incubation period, and associated findings, frequently are more helpful in distinguishing viral infections than is the exanthem itself. Enteroviruses are the leading cause of exanthematous diseases, with more than 30 types associated with rash illnesses, some of which also cause mucosal lesions.[35,43,44] Although neonates and young infants can have diffuse macular or blotchy rashes, exanthem at peak ages for enteroviral exanthematous diseases (especially due to echoviruses 4, 9, and 16 as well as coxsackieviruses A9 and B5) usually consists of rubelliform (maculopapular discrete, nonconfluent) lesions beginning on the face and upper trunk and spreading to the extremities.[44] An important exception is hand-foot-mouth disease (usually due to coxsackievirus A16, followed by A5, A6, A9, A10, B1, and B3, and enterovirus 71), in which buttock and peripheral distribution of vesicular or rubelliform lesions is characteristic. The exanthem of coxsackievirus A6 can be more widespread and varied with vesiculobullous, petechial, or eczema herpeticum−like presentation termed *eczema coxsackium*.[45] Rashes during viral infections due to influenza A and B, parainfluenza, and respiratory syncytial virus (especially in young children) probably occur more than occasionally, always are rubelliform, are frequently present for less than 24 hours, and spread from the head to the trunk and extremities.[35]

Rash occurs in 2% to 8% of adenoviral infections, and adenovirus types 1, 2, 3, 4, 7, and 7a have been isolated most frequently[44];

lesions are distributed as with influenza and usually are rubelliform, occasionally are morbilliform (maculopapular confluent patches), and rarely are EM like. Mucocutaneous and systemic manifestations of measles can simulate KD, the rash being least differentiating; prominent cough, coryza, and eventual purulent conjunctivitis distinguish measles. Similarly, the prominent respiratory tract symptoms caused by *Mycoplasma pneumoniae* distinguish this infection; maculopapular rashes (5% to 15% of cases), consisting of vesicular or bullous, papular, petechial, urticarial, or EM-like lesions have been described.[46]

Classically, staphylococcal toxic shock is associated with diffuse erythroderma, with a flushed, sunburned appearance (without discrete lesions, tenderness, or induration) especially on the face, trunk, and proximal extremities. Streptococcal scarlet fever or scarlatina is associated with a diffuse, fine maculopapular rash, which is palpable, sandpaper like, and prominent on the trunk and proximal extremities; exaggeration of erythema in skinfolds (Pastia sign) is characteristic and is dramatic in the groin when present. Children with staphylococcal exfoliative toxin syndrome commonly have crusted, exudative, infective conjunctivitis, or paranasal lesions, in addition to generalized nonexudative exfoliation (Fig. 13.2). Frequently, toxin-mediated exanthems overlap, presumably because more than one toxin is encoded.

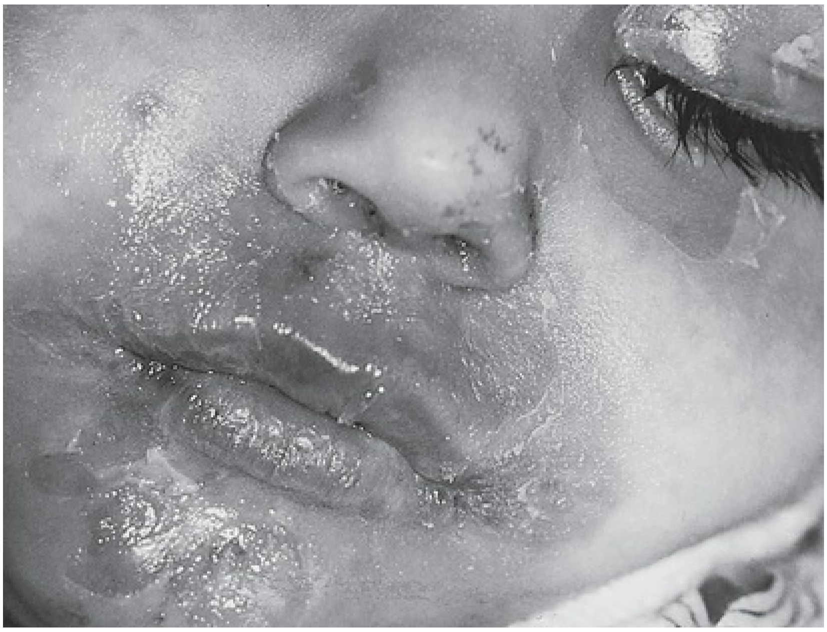

FIGURE 13.2 Four-year-old boy with staphylococcal

exfoliative toxin disease. Note characteristic paper-thin desquamation of skin on eyelid and impetiginous infection around the nose and chin.

Extremity Changes

Indurative erythroderma with frank edema of the distal extremities probably is the most helpful differentiating physical finding in some mucocutaneous syndromes, reflecting inflammatory vasculitis (KD), vascular dilation (toxic shock syndromes), or infective vasculitis (RMSF). Indurative erythroderma occurs in viral infections or SJS but is confined to contiguous sites of obvious exanthem. The demarcated, socks or gloves distribution of erythema and induration in KD is dramatic on occasion, as are digital cyanosis and gangrene (Fig. 13.3). When toxic or septic shock leads to peripheral ischemia, low blood pressure, weak pulse, and pale, cool extremities are expected. Parvovirus B19 and some herpesviruses also cause socks and gloves syndrome (especially in older children), with initial erythema and edema of dorsum and palms and soles with progression to papules and purpura, which is well demarcated at ankles and wrists.[47]

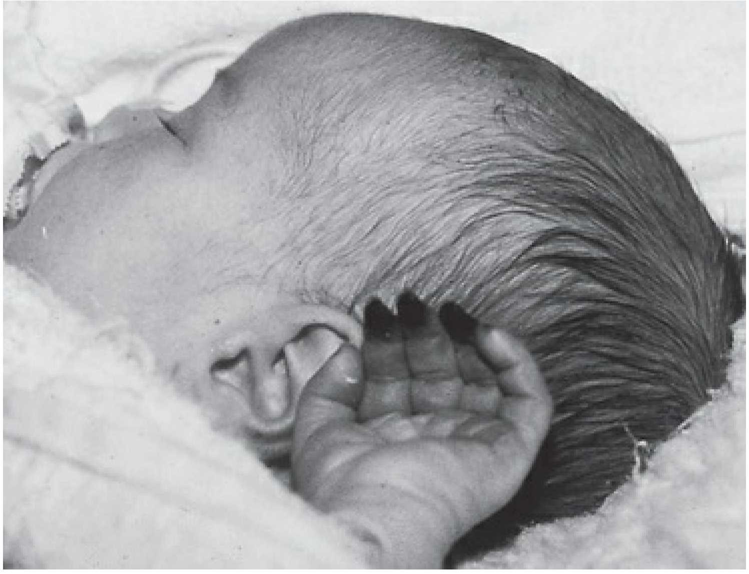

FIGURE 13.3 Six-week-old boy with the infantile polyarteritis nodosa form of Kawasaki disease. Note the dusky fingers with distal gangrene.

Evolution and Resolution

The exanthem of KD evolves, with waning, waxing, and migrating over days; that of toxic shock and exfoliative syndromes is rapidly progressive; and viral exanthems characteristically appear days after onset of systemic illness and evolve at one site while progressing to others. Desquamation occurs during the crescendo phase of staphylococcal exfoliative toxin syndromes, but during the decrescendo phase of KD, and only during the convalescent phases of staphylococcal and streptococcal toxic shock and scarlet fever. Desquamation of palms and soles is likely to be a full-thickness loss (as if molted) after KD, streptococcal scarlet fever, and toxic shock. In KD, unlike bacterial toxin-mediated diseases, total body desquamation does not occur or is fine and superficial, occurring in only about 10% of patients, particularly in the groin and perineal area. Hair loss and nail bed deformities (i.e., grooves [Beau lines], pits, and transverse [red] lines) are well described after KD but can occur after other highly febrile illnesses, after coxsackievirus A6,[45] or with hypotension or ischemia, such as invasive bacterial infection, toxic shock, and RMSF.

Other Clinical Features and Cardinal Feature

Clinical features other than mucocutaneous signs or symptoms, alone or in combination, can provide valuable clues to diagnosis. A partial listing is given in Table 13.1. Inflammation at multiple sites is typical of KD, anterior uveitis being quite specific among diagnoses considered. Transient hydrops of the gallbladder manifesting as right upper quadrant abdominal pain, tenderness, and fullness is a common finding in KD but is nonspecific, also described with staphylococcal toxic shock,[19] streptococcal scarlet fever,[48] enteric fever,[49] leptospirosis, Epstein-Barr virus mononucleosis,[50] neonatal group B streptococcal septicemia, and asphyxia, and during parenteral alimentation.[51]

Infants younger than 6 months with KD are especially prone to a rapidly progressive course and severe vascular complications[21,52,53] and can lack classical features, such as exanthem and erythematous conjunctivae. Extremely high fever, inconsolable irritability, respiratory distress, and cardiac gallop murmur with hepatomegaly can be clues. Aneurysmal dilation of multiple vessels can occur;

pulsatile masses in the axillae or groin can sometimes be detected within days of onset of fever.

Delineating the predominant complaint, or cardinal feature, of the child's illness aids in establishment of a correct diagnosis (see Table 13.1). Prodromal fever, diarrhea, and then profound prostration and hypotension are predominant in staphylococcal toxic shock but also can occur in streptococcal toxic shock. Streptococcal toxic shock frequently has a specific prodrome; the clinical picture can be dominated by extremely painful but apparently minor soft tissue infection, followed by sudden inexorable shock and coagulopathy.

Children with staphylococcal exfoliative toxin syndrome have variable degrees of illness, depending on age and presence of bloodstream or focal infection; the rapidly evolving exanthem with loss of skin in sheets as well as purulence around eyelids and nose dominate the clinical picture. Edematous, bleeding, black eschar on the lips, and oral mucosal denudation are dramatic findings in SJS; in some cases, inflammatory necrosis of respiratory or intestinal tract mucosa causes wheezing, odynophagia, and other symptoms. In viral illnesses, the mucocutaneous features broaden the differential diagnosis, but other symptoms (such as cough, hoarseness, sore throat) commonly dominate the patient's or parent's complaints; general debilitation usually is modest, and the epidemiologic setting heightens the likelihood of a specific diagnosis.

Table 13.2 summarizes the differentiating features of classic staphylococcal toxic shock (associated with TSST-1 and enterotoxin B) and streptococcal toxic shock (associated with SPE A or B and, possibly, bacterial proteases). Although these syndromes are similar superficially, the evolution of clinical symptoms, complications, and outcomes frequently is distinctive. Staphylococcal toxic shock usually has a dramatic onset and rapid progression. Focal infection is present in most nonmenstrual pediatric cases but can be relatively minor (e.g., sinusitis, surgical wound).[54,55] Streptococcal toxic shock usually has a less abrupt onset of symptoms, with initial malaise and myalgia and then complaints of severe pain, hyperesthesia, or hypoesthesia at an apparently minor soft tissue site of infection.[41,42,56] Nonexudative pharyngitis is the occasional primary site of streptococcal infection, with a complaint of sore throat out of proportion to the findings.[57] Many children with streptococcal toxic shock have been brought for medical attention one or more times before the onset of catastrophic multiorgan system failure and shock.[58] A possible potentiating role of nonsteroidal anti-inflammatory drugs in invasive streptococcal disease has been questioned[59] and not excluded by case-control studies.[60,61]

Diagnosis and Empiric Therapy

The best working diagnosis, barring the presence of pathognomonic features, is made on clinical grounds. Laboratory findings infrequently confirm a diagnosis at the time therapy must be given. Brisk elevations of acute-phase reactants are supportive laboratory findings in KD (and are variably present in SJS); white blood cell count less than 15,000/mm^3, erythrocyte sedimentation rate less than 40 mm/hour, C-reactive protein less than 3 mg/dL, or platelet count less than 200,000/mm^3 are negative indicators for KD[21] (with important exception of low platelets in patients with severe shock-like presentation[23]). Leukemoid reaction with neutrophil count exceeding 30,000/mm^3 frequently occurs in very young infants with the infantile polyarteritis presentation of KD; anemia is universal.[52] These can be important clues to the diagnosis when mucocutaneous features are absent.

Leukocytosis is not expected in enteroviral infections. Leukocyte counts are less than 15,000/mm^3 in 90% of children hospitalized with influenza; leukopenia occurs in approximately 25%.[27,34] In a study of 105 children hospitalized with adenoviral infection, the mean peripheral leukocyte count was 13,300/mm^3 (10% had counts >20,000/mm^3), and almost 30% had an erythrocyte sedimentation rate higher than 40 mm/hour.[62]

Thrombocytosis is expected in KD but only in the second week of illness. Thrombocytopenia is described in rare cases of KD, usually unassociated with consumption coagulopathy.[23,63] Thrombocytopenia is common in invasive bacterial infection and toxic shock syndromes and occurs early in RMSF and ehrlichiosis[12]; modest thrombocytopenia can occur with uncomplicated enteroviral infections. A normal or low, rather than high, neutrophil count with extreme left shift is a typical effect of bacterial toxins[64];

thrombocytopenia and consumption coagulopathy (with extremely low erythrocyte sedimentation rate) also are common. Pyuria without hematuria is common in KD but infrequent in other conditions except SJS.

Empiric therapies are shown in Table 13.1, and conditions other than SJS are discussed in specific chapters. Prompt and aggressive antibiotic and supportive therapies are lifesaving in invasive bacterial infections and in staphylococcal exfoliative toxin syndrome in young infants. Antibiotic therapy may be beneficial in staphylococcal toxic shock, especially to treat focal infection and to prevent recurrence, but aggressive reversal of hypovolemia and cardiovascular shock is paramount. The important challenges in streptococcal toxic shock are (1) halting microbial replication and toxin production; (2) reversing tissue ischemia, acidosis, hypovolemia, and hypotension; and (3) supporting multiorgan failure related to diffuse thromboemboli. Data from animal models of streptococcal necrotizing myositis, as well as clinical observations, suggest that clindamycin is superior to β-lactam agents for treatment.[57,65]

Corticosteroid therapy should not be initial treatment for KD, is not indicated in staphylococcal exfoliative toxin syndrome or in staphylococcal or streptococcal toxic shock, and is controversial in SJS.[66] Aggressive care in burn units for children with SJS or toxic epidermal necrolysis with more than 10% skin loss improves outcome.[67] Many experts would give a 5-day trial of corticosteroids to a subset of children with SJS who are toxic and have mucosal involvement in addition to the mouth, skin eruption for 3 days or less, and less than 20% skin denudation.[25] Excess rate of infections[68] and mortality in drug-induced toxic epidermal necrolysis[67] have been reported with use of corticosteroids in uncontrolled studies. Patients with SJS or TEN onset in the setting of prior exposure to corticosteroids might have prolonged latency to disease onset and longer duration of disease progression.[69]

Therapy with immune globulin intravenous (IGIV) is critical for optimal outcome in patients with KD[21,22] and is lifesaving for very young infants.[52] No randomized prospective study with adequate power has been performed to evaluate IGIV therapy in staphylococcal or streptococcal toxic shock. Case reports and retrospective, matched case-control studies in adults suggest a potential benefit. Dosage used was 500 mg/kg/day × 5 days for staphylococcal disease and 2 g/kg once for streptococcal disease.[70] A European randomized, double-blind, placebo-controlled trial of IGIV (1 g/kg on day 1 followed by 500 mg/kg on days 2 and 3) for streptococcal toxic shock[71] showed trend of benefit,[72] but a multicenter retrospective study in US children did not.[73] Another European prospective comparative observational study in adults demonstrated improved survival in streptococcal toxic shock syndrome with use of either IGIV or clindamycin, but groups were not similar in severity of infection.[74] Anecdotal reports and predominantly retrospective case series of use of IGIV for severe SJS suggest possible beneficial effect but are conflicting.[66,75,76]

Fever Without Localizing Signs

Ravi Jhaveri, Eugene D. Shapiro

Most young children with fever and no apparent focus of infection have self-limited viral infections that resolve without treatment and are not associated with significant sequelae. However, a small proportion of young children with fever who do not appear to be seriously ill may be seen early in the course of a bacterial infection that could progress to bacteremia or meningitis. Despite numerous studies that have attempted to identify the febrile child who appears well but has a serious infection and to assess the effectiveness of potential interventions, no clear answers have emerged.[1–4] Studies show that parents usually are more willing than physicians to assume the small risk of serious adverse outcomes in exchange for avoiding the short-term adverse effects of invasive diagnostic tests and antimicrobial treatment.[5,6] The best approach to the treatment of the febrile child combines informed estimates of risks, careful clinical evaluation and follow-up of the child, and judicious use of diagnostic tests.[7]

Etiologic Agents

The list of microbes that cause fever in children is extensive. Relative importance of specific agents varies with age, season, and associated symptoms. The goal of this chapter is to assist in identifying the febrile child with a serious bacterial infection (SBI).

Table 14.1 shows the most common causes of SBI in children younger than 3 months.[8–12] The division at 1 month is not absolute; considerable overlap exists. Receipt of vaccines typically administered at 2 months also reduces the risk of SBI. Certain viruses, notably herpes simplex, influenza, and enteroviruses, can cause serious infections in neonates, mimicking septicemia and beginning as fever with no apparent focus of infection. Less serious viral infections are the most common causes of fever in children of all ages.

TABLE 14.1

Age-Related Causes of Serious Bacterial Infections in Very Young Infants

Age Group	Causative Bacteria
BACTEREMIA OR MENINGITIS	
<1 month	*Escherichia coli* Other enteric gram-negative bacilli
	Group B *Streptococcus*
	Streptococcus pneumoniae
	Staphylococcus aureus
	Salmonella spp. *Neisseria meningitides*
	Streptococcus pneumoniae *Listeria monocytogenes*
1–3 months	*Escherichia coli* Other enteric gram-negative bacilli Group B *Streptococcus*
	Salmonella spp.
	Neisseria meningitides
OSTEOARTICULAR INFECTIONS	
<1 month	Group B *Streptococcus*
	Staphylococcus aureus
1–3 months	*Staphylococcus aureus*
	Group B *Streptococcus*
	Streptococcus pneumoniae
URINARY TRACT INFECTION	
0–3 months	*Escherichia coli*
	Other enteric gram-negative bacilli
	Enterococcus species

In children between 3 and 35 months of age, most bacterial infections with no apparent focus are caused by *Streptococcus pneumoniae* (in unimmunized children), *Neisseria meningitidis,* or *Salmonella* spp. infection (which often is associated with symptoms of gastroenteritis). Because universal administration of pneumococcal and *Haemophilus influenzae* type b (Hib) conjugate vaccines, Hib has become rare, and the incidence of infection with *S. pneumoniae* has fallen substantially.[13,14] Other common causes of invasive bacterial infections in these children, such as *Staphylococcus aureus,* are usually associated with identifiable focal infections.

Epidemiology

Children Younger Than 3 Months

The risk of serious bacterial infection varies with age. Although longitudinal studies have shown that only 1% to 2% of children are brought to medical attention for fever during the first 3 months of life, a greater proportion of febrile infants has serious bacterial infections than older children.[15–18] Risk is greatest during the immediate neonatal period and through the first month of life, and risk is heightened for infants born prematurely.

In a prospective study conducted by investigators at the University of Rochester, factors were identified that indicate a low risk of serious bacterial infection in febrile infants younger than 3 months.[19] Among 233 infants who were born at term with no perinatal complications or underlying diseases, who had not received antibiotics, and who were hospitalized for fever and possible septicemia, 144 (62%) were considered unlikely to have a serious bacterial infection and fulfilled all of the following criteria: no clinical evidence of infection of the ear, skin, bones, or joints; white blood cell (WBC) count between 5000 and 15,000/mm^3; less than 1500 band cells/mm^3; and normal urinalysis results. Only 1 (0.7%) of the 144 infants had a serious bacterial infection (i.e., *Salmonella* gastroenteritis), and none had bacteremia. In contrast, among the 89 infants who did not meet these criteria, 22 (25%) had a serious bacterial infection ($P < 0.0001$) and 9 (10%) had bacteremia ($P < 0.0005$).

Many studies have largely corroborated results of the Rochester study.[11,12,20–25] Although investigators have used slightly different criteria to define young febrile infants at low risk for serious bacterial infection (and some investigators excluded children younger than 1 month old), all found that the risk of a serious bacterial illness in the group defined as being at low risk is very low. Approximately 10% of young febrile infants have urinary tract infections (UTIs), largely due to *Escherichia coli*, and 10% of this group (1% overall) have concomitant bacteremia or meningitis.[11,12,26]

In a meta-analysis of studies of febrile children younger than 3 months, the risks of serious bacterial illness, bacteremia, and meningitis were 24.3%, 12.8%, and 3.9%, respectively, for high-risk infants and 2.6%, 1.3%, and 0.6%, respectively, for low-risk infants.[15] The negative predictive value (NPV) for serious bacterial illnesses among infants fulfilling low-risk criteria ranged from 95% to 99%, and the NPV was 99% for bacteremia and 99.5% for meningitis.[15] Although the risk of serious bacterial infection is high among febrile infants younger than 3 months of age with no apparent focus of infection, clinical and laboratory assessment can identify the slightly more than 50% of infants at very low risk.

An observational study of more than 3000 infants younger than 3 months of age with fever greater than 38°C treated by practitioners and reported as part of the Pediatric Research in Office Settings Network found that 64% were not hospitalized.[4,27] Practitioners individualized management and relied on clinical judgment; guidelines were followed in only 42% of episodes.[4,27,28] Outcomes of the children were excellent. If the guidelines had been followed, outcomes would not have improved, but there would have been substantially more laboratory tests performed and more hospitalizations.[4]

Risk of serious bacterial illness in young infants has fallen further due to the marked reduction in early-onset group B streptococcal infections because of the effectiveness of peripartum antimicrobial prophylaxis of pregnant women with positive screening test results for colonization with group B S*treptococcus*.[29] In febrile children younger than 3 months of age who have an identified viral infection such as influenza, respiratory syncytial virus (RSV), or enteroviruses, the risk of a serious bacterial infection other than a UTI falls to almost zero.[24,30–33]

Children Older Than 3 Months

In the 1970s and 1980s, there was concern about occult bacteremia in febrile children between 3 months and 24 to 36 months of age.[34] Studies performed in that era showed that some children 3 months of age or older with fever who did not appear to be toxic and who had no apparent focus of infection had bacteremia, most often due to *S. pneumoniae* but occasionally due to Hib or *N. meningitidis.*[34–41] In some instances, serious focal infections such as meningitis developed in children with occult bacteremia.

The concern about progression to focal infections resulted in protocols being developed to identify and intervene for infants at high risk. Protocols emphasized routine blood cultures and empiric antibiotic administration for many febrile children in this age group.[28] These practices discounted several facts. First, most children with occult bacteremia have transient infection and recover without antimicrobial therapy and without developing a serious complication (e.g., meningitis, septic shock).[28,42,43] Second, risk of meningitis complicating occult bacteremia varies with bacterial species (*N. meningitidis* ≫ Hib ≫> *S. pneumoniae*).[35] Third, universal vaccination against Hib led to elimination in vaccinated infants of the most concerning occult bacteremia, and subsequent use of conjugate pneumococcal vaccine eliminated almost all other cases of occult bacteremia.[44–49]

The risk of UTI in well-appearing febrile children in this age group has not changed significantly over the years. Several studies have shown that the rate of UTI varies among different populations (e.g., girls vs. boys, uncircumcised vs. circumcised) within this age group and varies with height and duration of fever. UTI should be considered as a potential source of SBI in these patients.[44,50]

Laboratory Findings and Diagnosis

Various diagnostic tests to quantify the risk of bacteremia and its complications have been assessed. They include the WBC count and differential count, microscopic examination of buffy coat of blood, erythrocyte sedimentation rate, C-reactive protein, procalcitonin, morphologic changes in peripheral blood neutrophils, and quantitative cultures of blood.[28,51–58] Clinical scales have been developed to help identify the febrile child with a serious illness.[59]

Unfortunately, no test has sufficient sensitivity and positive predictive value (PPV) or NPV to be clinically useful for an individual patient. In the era before conjugate vaccinations for Hib and *S. pneumoniae,* several studies examined the risk of bacteremia among children with a temperature higher than 40°C and in those with fever and a WBC count of at least 15,000/mm.[3,41,51,60] The PPV of the tests for bacteremia was only about 15%. In the current era of low incidence and unconfirmed predictive value of WBC for remaining pathogens, laboratory testing no longer is justified.[1,7,45,47]

Making a laboratory-confirmed diagnosis of a viral infection significantly reduces the likelihood that a febrile infant has a concomitant bacterial infection (with the exception of a UTI). This currently holds true for influenza, RSV, and enterovirus, and in the future, it will likely be true for many other respiratory viruses (e.g., human metapneumovirus, parainfluenza virus, coronavirus) that are being diagnosed with multiplex polymerase chain reaction (PCR) technology. One study showed that incorporating viral diagnostics into the initial evaluation of febrile infants reduced the length of hospitalization and healthcare costs.[61]

Management

Although there is no single correct approach to the management of febrile infants without localizing signs who appear well, studies have provided data based on which informed decisions can be made.[7] There is general agreement that febrile children who are very young (i.e., variously considered to be younger than 3, 2, or 1 month of age) should be managed differently from older children.

Children Younger Than 3 Months

Because of the substantially greater risk of serious infections in very young infants with fever and the difficulty in assessing the degree of wellness accurately, pediatricians have approached the management of these cases conservatively. Some clinicians adhere to a protocol of treating all young infants with fever and no apparent focus of infection with broad-spectrum antimicrobial agents administered intravenously in the hospital until the results of cultures of the blood, urine, and cerebrospinal fluid (CSF) are known.[62] Although perceived as the safe approach, it incurs considerable financial cost and risk of iatrogenic complications and of diagnostic misadventures associated with hospitalization.[63–65] These risks include errors in the type and dosage of drugs, complications of venous cannulation (e.g., phlebitis, sloughing of the skin), and nosocomial infections. Hospitalization of a young infant is a major disruption for the family and may potentiate development of the vulnerable child syndrome.[66]

Investigators have found that selected young infants with fever can be treated expectantly without hospitalization.[4,7,19,21,27,67] Consequently, many experts think that febrile infants between 4 and 12 weeks of age with no apparent focus of infection who appear well or have a laboratory-documented viral infection can be treated without additional laboratory tests or hospitalization, provided that careful follow-up is ensured.[7] Others prefer to confirm laboratory criteria that predict low risk (sometimes including a normal CSF analysis result). Some providers observe the patient very closely without giving antimicrobial therapy; others treat all such infants for 2 days with a single daily dose of ceftriaxone (50 mg/kg) administered parenterally while awaiting the results of blood, urine, and CSF cultures. Either approach, if careful and vigilant, is defensible.

Before an antimicrobial agent is administered, cultures of the blood, urine, and CSF should be obtained. Rapid tests for specific viral pathogens are widely available, can aid decisions about managing patients, and can reduce the duration of hospitalization or eliminate the need.[7,31–33,68] Febrile infants at low risk for serious bacterial infection for whom adequate home observation and follow-up cannot be ensured should be hospitalized and can be observed without antimicrobial treatment. If the child appears well, doing so is reasonable and avoids the adverse side effects of antimicrobial agents and intravenous cannulation, shortens the duration of hospitalization, and saves money without placing the child at significant risk for complications.[21,27,67]

Most infants with fever who are younger than 1 month should be hospitalized and treated with antimicrobial therapy (with or without acyclovir for herpes simplex virus), although in selected instances, hospitalization without antimicrobial treatment or outpatient management after laboratory evaluations, including CSF analysis, may be reasonable. If a decision is made to administer antimicrobial agents intravenously, ampicillin (100 to 200 mg/kg per day every 6 hours) plus gentamicin (7.5 mg/kg per day every 8 hours) or a third-generation cephalosporin (e.g., ceftriaxone, 50 mg/kg per day in one dose; cefotaxime, 150 mg/kg per day every 8 hours) could be chosen. Ampicillin and gentamicin is a well-established combination with narrower spectrum of antimicrobial activity than ceftriaxone and excellent effectiveness against group B *Streptococcus*, *Listeria monocytogenes,* and many enteric gram-negative rods. Because of the rising incidence of ampicillin-resistant *E. coli* and the rarity of listeriosis in recent large studies, a regimen with a third-generation cephalosporin without ampicillin offers coverage for the few infants who have bacteremia or meningitis with a UTI due to ampicillin-resistant *E. coli*.[11,12,25] No study has directly assessed the relative risks and benefits of either regimen. Before initiating antimicrobial treatment with any regimen, cultures of the blood, urine (obtained by urethral catheterization or suprapubic aspiration of the bladder), and CSF should be obtained.

Children 3 Months of Age and Older

Children 3 months of age and older who appear well and have no apparent focus of infection can be evaluated clinically without laboratory tests or treatment with antimicrobial agents, with the exception of examination of the urine. In the current conjugate vaccine era, blood culture isolates are substantially more likely to be contaminants than to be pathogens.[7] Substantial evidence suggests that obtaining blood cultures routinely from these children has little impact on outcome, although false-positive blood culture results lead to substantial unnecessary costs.[69,70]

The following approach seems appropriate. The febrile child should be carefully assessed for a focus of infection, including UTI, and if a focus is found, the child should be treated according to likely pathogens. If the child appears toxic, appropriate cultures and diagnostic tests should be performed, and antimicrobial treatment (usually with cefotaxime, 150 mg/kg per day in divided doses every 8 hours, or ceftriaxone, 50 mg/kg once daily) should be initiated; some physicians add vancomycin (40 mg/kg per day in divided doses every 6 to 8 hours). Most of these children should be hospitalized.

If no focus is found and the child does not appear toxic, no diagnostic tests are indicated routinely. Parents should be instructed to look for signs that a more serious problem is developing (e.g., persistent irritability or lethargy, inattentiveness to the environment). Serial observations should be planned that permit subsequent clinical and laboratory evaluation and antimicrobial treatment as indicated. If a practitioner encounters a febrile child older than 4 months of age who is unimmunized or partially immunized, a more aggressive plan for evaluation and management may be warranted.

Other Considerations

This chapter focuses on invasive bacterial infections, particularly bacteremia, as a cause of fever without apparent focus. Although other serious illnesses such as autoimmune diseases and inflammatory bowel disease can manifest as fever without a focus of infection, they are rare and come to attention because of persistence or recurrence of fever (see Chapter 15).

Prolonged, Recurrent, and Periodic Fever Syndromes

Kalpana Manthiram, Kathryn M. Edwards, Sarah S. Long

Diagnosing and treating patients with prolonged, recurring, or periodic fever requires extensive review of signs and symptoms to establish the onset and cardinal features of illness, to define the exact fever pattern, and to understand the context of illness within the patient's family. It also requires comprehensive medical and family histories.

Defining fever patterns (Box 15.1) is essential in prioritizing the differential diagnosis and investigation.[1] A comprehensive physical examination can identify target organ abnormalities of potential infectious and noninfectious diseases. In children with prolonged fever, laboratory testing should include simple screening, and targeted investigation then is performed for specific organ systems as identified by the history, physical examination, exposures, or prioritized clinical differential diagnosis (Box 15.2).[1] For children with periodic fever, the main goal of performing screening laboratory tests is to confirm normal organ system function, direct the clinician to a specific disorder (e.g., recurrent urinary tract infection), or support the diagnosis of a noninfectious periodic fever syndrome. In evaluating children with any fever pattern, casting a broad net of serologic testing for unusual infectious agents is rarely fruitful in the absence of a specific exposure history or compatible clinical findings.

Box 15.1

Fever Patterns of Illness Used for Establishing a Diagnosis

Prolonged fever: A single illness in which the duration of fever exceeds that expected for the clinical diagnosis (e.g., >10 days for viral upper respiratory tract infections; >3 weeks for mononucleosis)

or

A single illness in which fever was an initial major symptom and subsequently is low grade or only a perceived problem

Fever of unknown origin: A single illness of at least 3 weeks′ duration in which fever >38.3°C occurs on most days and the diagnosis remains uncertain after 1 week of intense evaluation

Recurrent fever: A single illness in which fever and other signs and symptoms wax and wane (sometimes in relation to discontinuation of antimicrobial therapy)

or

Repeated unrelated febrile infections of the same organ system (e.g., sinopulmonary, urinary tract)

or

Multiple illnesses occurring at irregular intervals and involving different organ systems in which fever is one variable component

Periodic fever: Recurring episodes of illness for which fever is the cardinal feature, other associated symptoms are similar and predictable, and the duration of episodes is days to weeks, with intervening weeks to months of complete well-being; episodes can have clockwork or irregular periodicity

Box 15.2

Physical Examination and Screening Laboratory Testing for Children With Prolonged, Recurrent, or Periodic Fever

Physical Examination

- Growth chart
- Thorough general examination
- Careful organ-specific examination
- Notation of mouth ulcers, exanthem, joint abnormalities, and lymph nodes

Tests

- Complete blood count with manual differential count of white blood cells[a]
- Erythrocyte sedimentation rate and C-reactive protein[a]
- Screening serum chemistry tests (and lactate dehydrogenase and uric acid levels for prolonged fever)
- Serum quantitative immunoglobulin levels
- Urinalysis
- Urine culture
- Chest plain radiograph (for prolonged fever)
- Other imaging only as directed by examination and other screening tests
- Blood culture (for prolonged fever)
- Serologic testing only as directed by examination, other screening tests and exposures
- Complete blood count performed during episode and wellness interval for periodic fever

Fever of Unknown Origin

Definition

The three criteria for fever of unknown origin (FUO) in Petersdorf and Beeson's landmark study of adults in 1961[2] were illness of more than 3 weeks duration, fever higher than 38.3°C on several occasions, and an uncertain diagnosis after 1 week of study in the hospital. A prospective, population-based study conducted in the 1990s with adults in the Netherlands used fixed epidemiologic entry criteria and a specific diagnostic protocol.[3,4] The classic definition of FUO was adjusted; immunocompromised patients were excluded, and 1 week of hospitalization was replaced with 1 week of intensive evaluation (usually including computed tomography [CT] of the abdomen), and pursuit of potential diagnostic clues.

In pediatrics, studies of FUO have used various definitions, with temperature thresholds between 38.0°C and 38.9°C and durations of fever ranging from 14 to 21 days.[5–9] Some required daily fever, but others required fever on multiple occasions. For purposes of our definition, FUO in children is considered only after a minimum of 14 days of daily documented temperature of 38.3°C or greater without apparent cause after performance of repeated physical examinations and screening laboratory tests. This definition assumes exclusion of protracted but waning symptoms from acute, self-limited respiratory tract infections, well-documented periodic fever, and repeated but unrelated episodes of fever with identifiable causes.

Almost one-half of children referred for FUO do not meet fever and exclusion criteria. The method of temperature measurement and the frequency and timing of fever must be carefully investigated. Temperature is interpreted with the use of norms for age and sex (Fig. 15.1).[10] At 18 months of age, mean rectal temperature for boys is 37.7°C with a standard deviation (SD) of 0.38°C; a rectal temperature of 38.5°C is less than 2 SD above the mean. Normal body temperature fluctuates on average by 0.5°C in adults and by as much as 1.5°C in children, and it typically peaks in the late afternoon or evening.[11,12] An asymptomatic toddler with low-grade fever in the evenings with normal physical examination findings may have a normal body temperature.

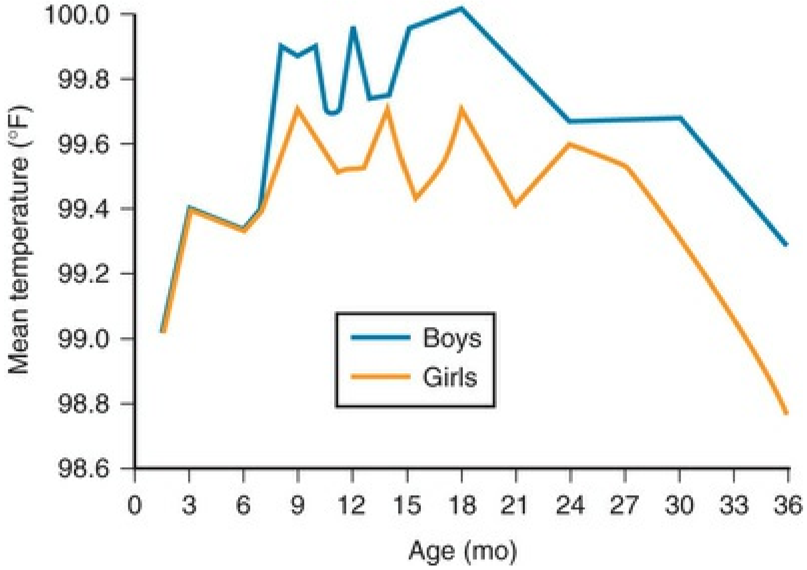

FIGURE 15.1 The normal mean rectal temperatures for boys and girls through 36 months of age are shown (100°F = 37.8°C). (Data from Bayley M, Stolz HR. Maturational changes in rectal temperature of 61 Infants from 1 to 36 months. Child Dev 1937;8:195.)

Etiology

In Petersdorf and Beeson's original paper, a high incidence of serious disease was found, with infections accounting for 36% of cases, neoplasms for 19%, collagen vascular diseases for 13%, and no diagnosis found in 7% of cases.[2] In a separate assessment of individuals with fever that did not exceed 38.3°C (even if protracted), diagnosis of significant illness was rare, and 30% of patients had no diagnosis, three-fourths of whom recovered spontaneously. In studies of FUO in children, decreasing stringency of entry criteria also correlated with increased likelihood of self-limited conditions.[5,9,13–17] When fever approaches 4 weeks' duration without a definable source, the rate of life-altering diagnoses such as malignancy and autoimmune or autoinflammatory disease rose to 40% in some series.[5,14,15]

In recent studies of FUO, probably because earlier diagnoses are made with imaging, serologic, or molecular diagnostic tests, a large proportion of patients who fulfill criteria have no identified diagnosis.[18] In a prospective, multicenter study of adults in the

Netherlands in 2007, 51% of patients had no cause of FUO found.[19] A similar trend has been seen in pediatrics.[18,20] In pediatric studies, 42% to 47% of patients with prolonged fever or FUO had no identified cause.[9,21] Most patients had spontaneous resolution of fever without sequelae.[5,6,21] In most recent decades, patients fulfilling criteria for FUO also are less likely to have serious, life-altering diagnoses.[6,21]

Limitations of published case series of FUO in children include small numbers; variations in the definition of FUO and investigation of subjects, study methodologies, and years and sites of study; and subspecialty referral biases.[22] A systematic review published in 2011 of 18 pediatric studies involving 1638 children divided studies into those performed in developed countries (i.e., 8 studies from three countries, all published more than 1 decade ago) and developing countries (i.e., 10 studies, with 8 published since 2000).[22] Overall, categories of diagnoses in developed and developing countries were remarkably similar: infection in 51%, malignancy in 6%, autoimmune or autoinflammatory diseases in 9%, miscellaneous noninfectious conditions in 11%, and no diagnosis in 23% of cases. Infectious causes were slightly more common in developing countries (56% vs. 42%), whereas finding no cause was more common in developed countries (31% vs. 18%). The infections diagnosed in 832 children included in the systematic review are shown in Table 15.1.[22]

TABLE 15.1

Reported Infectious Causes of Fever of Unknown Origin in 832 Children in Developed and Developing Countries

Infectious Cause	Developed Countries[a] (*N* = 275)	Developing Countries[b] (*N* = 557)	Most Common Agents and Infections in Descending Order of Frequency
Bacteria	56%	61%	Developed: urinary tract, osteomyelitis, tuberculosis, *Bartonella*, septicemia (not specified), *Salmonella*, *Brucella*
			Developing: *Brucella*, urinary tract, *Salmonella*, tuberculosis, abscess (not specified), septicemia (not specified)
Viruses	15%	3%	Developed: Epstein-Barr virus, cytomegalovirus, enterovirus
			Developing: Epstein-Barr virus, cytomegalovirus, human immunodeficiency virus
Fungi	1%	0.2%	Developed: *Blastomyces*, *Histoplasma*

Parasites	2%	14%	Developed: *Leishmania*
			Developing: *Leishmania, Plasmodium*
Infectious syndrome without pathogen	26%	22%	Developed: viral syndrome (not specified), pneumonia, meningitis
			Developing: pneumonia, respiratory tract (not specified), infectious mononucleosis, viral syndrome (not specified)

[b] Tunisia, India, Turkey, Poland, Argentina, Serbia, Georgia, and Kuwait.

From Chow A, Robinson JL. Fever of unknown origin in children: a systematic review. World J Pediatr 2011;7:5–10.

Children younger than 6 years of age are more likely to have an infectious cause of fever than older children, who are more likely to have autoimmune and autoinflammatory disorders.[8] In older pediatric studies of FUO, bacterial pathogens and respiratory tract infections were responsible for a larger portion of disease compared with more recent studies.[9,20,21] Epstein-Barr virus (EBV), *Bartonella henselae,* urinary tract infections, and osteomyelitis (especially of spine and pelvic bones) are the most common infections identified in recent studies.[7,9,21] Agents that produce granulomatous infections (i.e., *Bartonella, Mycobacterium, Salmonella, Histoplasmosis, Brucella,* and *Francisella* spp.) cause FUO disproportionately and frequently involve the visceral organs, reticuloendothelial system, and bone marrow.[23]

Box 15.3 summarizes noninfectious causes of FUO. Leukemia and lymphoma are the most common malignancies diagnosed, and juvenile idiopathic arthritis, inflammatory bowel disorders, and systemic lupus erythematosus are the most common autoinflammatory and autoimmune disorders, but they may be variously classified.[22] Kawasaki disease is the most common miscellaneous diagnosis in developed countries.[22] Table 15.2 shows some discriminating features of infectious and noninfectious causes of FUO.[24–63] For infections, the agents, sites, and clinical manifestations are typical but are subtle and overlooked or are associated with an insidious or prolonged course.[1,23,64]

TABLE 15.2

Discriminating Features of Infectious and Noninfectious Causes of Fever of Unknown Origin

Causes of Fever	Exposure or Condition	Features	Diagnostic Method
INFECTIOUS CAUSES			
Salmonella spp.[24–27]	Exposure to endemic pathogen; immigration; turtles and other animals; foods	High spiking fever; overlooked or mild abdominal pain	Culture blood, stool; culture bone marrow (especially if antibiotic given)
Bartonella henselae[9,28–31]	Kittens; healthy and immunocompromised people	Mild abdominal complaints, headache; lymphadenopathy usually absent; hepatic, splenic, or bone marrow granulomas	Serology; histology
Epstein-Barr virus[9,32]		Typhoidal course without classic mononucleosis symptoms or signs;	Serology; plasma PCR

		malaise; pneumonia	
Yersinia enterocolitica[33]	Animals, especially pigs; pork chitterlings	Abdominal pain; hepatic or splenic granulomas or abscesses; exanthems	Culture blood, stool, biopsy specimen; serology
Mycobacterium tuberculosis[34–36]	Exposure to symptomatic adults; endemic; immigration; HIV	Extrapulmonary, miliary, disseminated disease	Chest radiograph; tuberculin skin test or interferon-γ release assay; culture gastric aspirate, bone marrow, or biopsy specimen
Nontuberculous mycobacteria[37]	HIV, malignancy, cystic fibrosis; occasionally healthy toddlers	Respiratory or gastrointestinal symptoms; mediastinal lymphadenopathy	Culture gastric aspirate, blood, stool, mediastinal or enteric biopsy specimen; histology
Plasmodium spp.[22,24]	Exposure to mosquitoes in endemic areas; rare in United States from mosquitos or blood transfusions	Persistent (early) or remitting spiking fever, splenomegaly; anemia	Wright stain blood smears, rapid malaria antigen detection test
Brucella spp.[38,39]	Unpasteurized dairy products; farm animals	High spiking fever, arthralgia, hepatomegaly; elevated hepatic transaminases; Coombs-positive anemia	Serology
Coxiella burnetii[40]	Unpasteurized dairy products; aerosol from parturient cats	Fever persistent 5–10 days or relapsing over months; elevated levels of hepatic transaminases	Serology
Francisella tularemia	Ticks, fleas, mites, deer flies; airborne or direct contact with animals	Ulceroglandular, typhoidal, pleuropneumonia	Serology
Leptospira spp.	Rodents, domestic animals	Persistent or biphasic fever, aseptic meningitis; hepatitis	Serology
Leishmania	Exposure to endemic pathogen; immigration	Insidious onset (2–6 months); hepatosplenomegaly; Coombs-positive anemia	Giemsa or Wright stain biopsy or aspirate specimen; culture bone; serology
Rickettsia, Ehrlichia, Anaplasma[9]	Exposure to ticks in endemic areas	Absent or atypical rash; headache	Serology; PCR; Wright stain of blood or CSF (morulae of *Anaplasma, Ehrlichia*)
Neisseria meningitidis (chronic)		Petechial exanthema	Culture of blood
Toxocara canis, T. cati	Dog and cat feces; pica	Hepatosplenomegaly; eosinophilia; hypergammaglobulinemia	Serology
HIV	Sexual or vertical	Hepatosplenomegaly;	PCR; serology

	acquisition	mononucleosis syndrome; hypergammaglobulinemia	blood or saliva
Endocarditis	Congenital or acquired heart disease, central venous catheter; occasionally no underlying condition found	Splenomegaly, new heart murmur; immune complex exanthems; anemia; HACEK organism from blood culture; persistently positive blood culture	Blood culture; echocardiogram; consideration of uncultivatable pathogens
Intra-abdominal or retroperitoneal abscess[22,41–43]	Appendicitis; surgery; urinary tract infection; *Staphylococcus aureus* bloodstream infection	Localized pain or tenderness; elevated inflammatory markers; positive blood culture	Computed tomography
Pelvic or vertebral osteomyelitis		Localized pain or tenderness; elevated inflammatory markers; positive blood culture	Magnetic resonance imaging
Odontogenic infection[44]	Dental caries	Painful teeth, discomfort with chewing or biting on tongue depressor; lung abscess; submandibular or submental lymphadenopathy; swelling, tenderness of face or jaw	Dental radiography
Kikuchi-Fujimoto disease[45,46]		Regional or generalized lymphadenopathy; elevated inflammatory markers	Biopsy or histology
Inflammatory pseudotumor[47–49]	History of nonspecific illness (presumed host-controlled infection)	Insidious; malaise, weight loss, vague abdominal pain or tenderness; anemia; elevated inflammatory markers	Abdominal computed tomography; biopsy or histology
NONINFECTIOUS CAUSES			
Kawasaki disease (incomplete)[50,51]		Asynchronous or incomplete features Kawasaki disease; elevated inflammatory markers; thrombocytosis	Clinical constellation; echocardiogram
Juvenile idiopathic arthritis[16,52]	Familial, sporadic	Hepatosplenomegaly, lymphadenopathy, exanthem; anemia, elevated inflammatory markers	Clinical constellation
Systemic lupus erythematosus	Familial, sporadic	Malaise, weight loss; then multisystem involvement (kidneys, joints, skin)	Serum antinuclear antibody, anti–double-stranded DNA, anti–smooth muscle antibody
Hemophagocytic lymphohistiocytosis[53,54]	Virus associated; familial; rheumatologic disorder	Severe, rapidly progressive illness; hepatomegaly, lymphadenopathy, exanthem; cytopenias; extreme elevations of inflammatory markers	Ferritin, triglyceride levels, other diagnostic criteria; macrophage phagocytosis blood cells; natural killer

			cell, CD8$^+$ T lymphocyte dysfunction
Vasculitis syndromes	Familial, sporadic	Specific hallmarks (renal, neurologic, stomatitis or perianal ulcers, uveitis, pulmonary)	Clinical constellation; specific autoantibodies; biopsy or histology
Sarcoidosis[55]	Geography; race	Fatigue, weight loss, leg pain; anemia, elevated inflammatory markers; mediastinal lymphadenopathy; uveitis	Clinical constellation; biopsy or histology; soluble interleukin-2 receptor level
Inflammatory bowel disease	Familial; sporadic	Linear growth failure, subtle gastrointestinal symptoms or abdominal tenderness; perirectal skin tag; iron deficiency anemia; elevated inflammatory markers	Abdominal computed tomography; barium study
Lymphoreticular malignancy[22,56–59]		Weight loss, fatigue; nonarticular bone pain; lymphadenopathy; cytopenias	Bone marrow or tissue biopsy
Drug hypersensitivity[60]	Prescription or nonprescription drug exposure	Preserved sense of well-being; exanthems; eosinophilia; organ dysfunction (renal, cardiac, pulmonary)	Clinical constellation; withdrawal of drug
Factitious fever or Munchausen syndrome by proxy[61]	Predisposing parent-patient dynamic	Discordant temperature and vital signs; discordant parent-measured temperature and urine temperature; normal inflammatory markers	Clinical constellation; medical validation temperature
Hypothalamic dysfunction, diabetes insipidus, dysautonomia, or absent corpus callosum[62,63]	Underlying condition; genetic syndrome; anatomic abnormality	Normal inflammatory markers; hypernatremia; no response to nonsteroidal anti-inflammatory drugs	Clinical constellation; laboratory tests and imaging

CSF, Cerebrospinal fluid; HACEK, *Haemophilus*, *Aggregatibacter* (previously *Actinobacillus*), *Cardiobacterium*, *Eikenella*, and *Kingella* genera; HIV, human immunodeficiency virus; PCR, polymerase chain reaction.

Approach to the Workup

For those with FUO, careful reassessment of the history and physical examination findings often reveals diagnostic clues that should be pursued with targeted testing (see Table 15.2).[5,6,65] FUO is more likely an unusual presentation of a common disease than an uncommon disease.[66] The workup typically is done in phases, the pace of which is determined by the progression and severity of symptoms and laboratory test results. Screening tests are performed on all patients, and specific serologic tests are guided by exposure histories and examination findings. Serology for EBV and *B. henselae* typically are sent early in the workup in patients with compatible clinical presentations due to the high frequency of these diagnoses.[7,9,65]

A chest radiograph should be performed for all patients regardless of symptoms. Other imaging is obtained selectively based on symptoms, physical examination findings, and test results. Abdominal ultrasound usually is performed for patients with abdominal symptoms, with abnormal levels of serum hepatic enzymes, or in whom hepatosplenic cat-scratch disease is suspected, but it may also have diagnostic utility for patients without localizing symptoms.[7,9]

CT of the sinuses is viewed as an early study for patients with symptoms of sinusitis. Chest CT may be indicated when granulomatous or embolic disease is suspected. For 28 children with prolonged fever, an abdominal CT scan was abnormal for 86% of the children in whom clinical features directed suspicion to the abdomen; the yield of the procedure for others was low.[67] In another study of 109 children with FUO, multiple modalities, including radioisotope scans and bone marrow biopsies, rarely led to a diagnosis.[7] Performing imaging studies in the absence of signs or symptoms of involvement of an organ system usually is not helpful. A definite normal interpretation of imaging studies is unusual, and any abnormal finding often leads to further studies, which can divert focus from a correct diagnosis.

Fluorodeoxyglucose position-emission tomography (FDG-PET) was thought to be a useful early test for adults in the Netherlands and in one meta-analysis in 2011.[19,68] However, FDG-PET has not been adequately studied in children with FUO. In a rigorously conducted, prospective study of FUO in adults for whom no potentially diagnostic clues were gleaned from the history or physical examination, scintigraphy, other imaging modalities, liver or bone marrow biopsy, and screening for endocrine abnormalities were not revealing of pathology.[4] The investigators recommended repeating a thorough history, physical examination, and first-level laboratory tests and waiting for diagnostic clues to appear.[4] This approach also is appropriate for children unless there is progression of weight loss or an abnormality found on examination or simple screening tests.

Prolonged Insignificant Fever, Prolonged Illness With Resolved Fever, and Fatigue of Deconditioning

One of the most frequent referrals to pediatric infectious disease subspecialists for prolonged fever is an adolescent with low-grade or falsely perceived fever or one whose fever has resolved but feels unwell and is unable to attend school and social activities. These patients require the same disciplined performance of history and examination as those with true FUO. For the subspecialist to offer a definitive opinion, the family must perceive that a thorough and thoughtful consultation has occurred. All laboratory test results, imaging studies, and biopsy slides should be reviewed. The findings listed in Box 15.4, evaluation of complaints, review of systems, and laboratory studies must suggest that no cryptogenic infection or serious medical condition is present.[1]

Box 15.4

Typical Findings for Patients With Fatigue of Deconditioning

Age older than 12 years

High level of achievement before illness

Family expectations high

Acute febrile illness with onset easily dated

Family and outside attention high

Multiple but vague complaints

Odd complaints of brief duration (<1 minute) (e.g., shooting pains at multiple sites; blindness; stereotypic, sporadic, unilateral tremors, jerks, or paralysis)

Tiredness but no daytime sleep or reversal of daytime and nighttime sleep

Model of chronic illness in family, recent loss of important person, change in family dynamic

Unusual cooperation and interest during interview and examination or unusual fearfulness and dependency on parent

Preserved or increased weight

Normal physical and neurologic examination findings

Normal results of screening laboratory tests

Discordance of a lengthy list of complaints with the normal findings of examination and laboratory tests is typical. The family's modus operandi centers on the patient. Prodded recitation of a typical 24-hour period of activity reveals a feeling of tiredness but no prolongation of time asleep. There is frequently a parental model of chronic illness or a recent change in extended-family dynamics (e.g., divorce, serious medical diagnosis, death). Deconditioning (i.e., diminution of physical strength, stamina, and vitality), loss of self-esteem, fear of failure to perform at the level of previous expectations, and secondary gain may contribute to the clinical state. The patient should be queried privately about potential abuse and for other informative insights.

Depression should be considered. Clues in depressed individuals include a feeling of persistent sadness, lack of self-worth, dislike of or wanting to hurt oneself, anger, marginalization, and a feeling of being disliked by others.[69] Fatigued individuals usually do not have these feelings, but they instead have increased somatic complaints and a tendency to internalize stress.[70]

In the past decade, neurally mediated hypotension and postural tachycardia have been postulated as mechanisms of persistent fatigue. Two studies of adults published in 2005 suggest that orthostatic instability is a common finding in healthy and fatigued individuals[71] and that among military recruits with orthostatic intolerance, endurance exercise training significantly improved the physiologic findings and symptoms.[72] In a formal study of 14 adolescents with orthostatic hypotension, symptoms and findings were attenuated by use of a static hand grip[73] (see Chapter 200).

Management of fatigue of deconditioning begins with a precise review of findings and conclusions about what the diagnosis is and is not.[1] Management is outlined in Box 15.5. It is a disservice to diagnose chronic fatigue syndrome, support home tutoring, or refer the patient to additional subspecialists for minor findings. The primary care pediatrician should set the tempo for reconditioning and monitoring. A personal fitness trainer may introduce a new positive relationship with the patient that separates the patient effectively from illness-enabling family dynamics.

Box 15.5

Management of the Patient With Fatigue of Deconditioning

Patient

- Validate symptoms as accurate.
- Explain that there is no serious disease.
- Prescribe incremental, forced return to school.
- Prescribe exercise.
- Predict increased symptoms in the process of reconditioning.
- Disallow school absence without examination that day by primary care provider.
- Reassure that there will be no expectation of achievement from performance.

Family

- Validate their concerns.
- Explain that symptoms could have been clues to serious conditions.

- Validate their medical pursuit.
- Describe organ-based normal findings in history, examination, and screening laboratory tests.
- Advise change of family focus from illness to health.
- Advise family to avoid asking, “How do you feel?”
- Elicit promise to patient of no expectation of achievement or performance.

Primary Physician

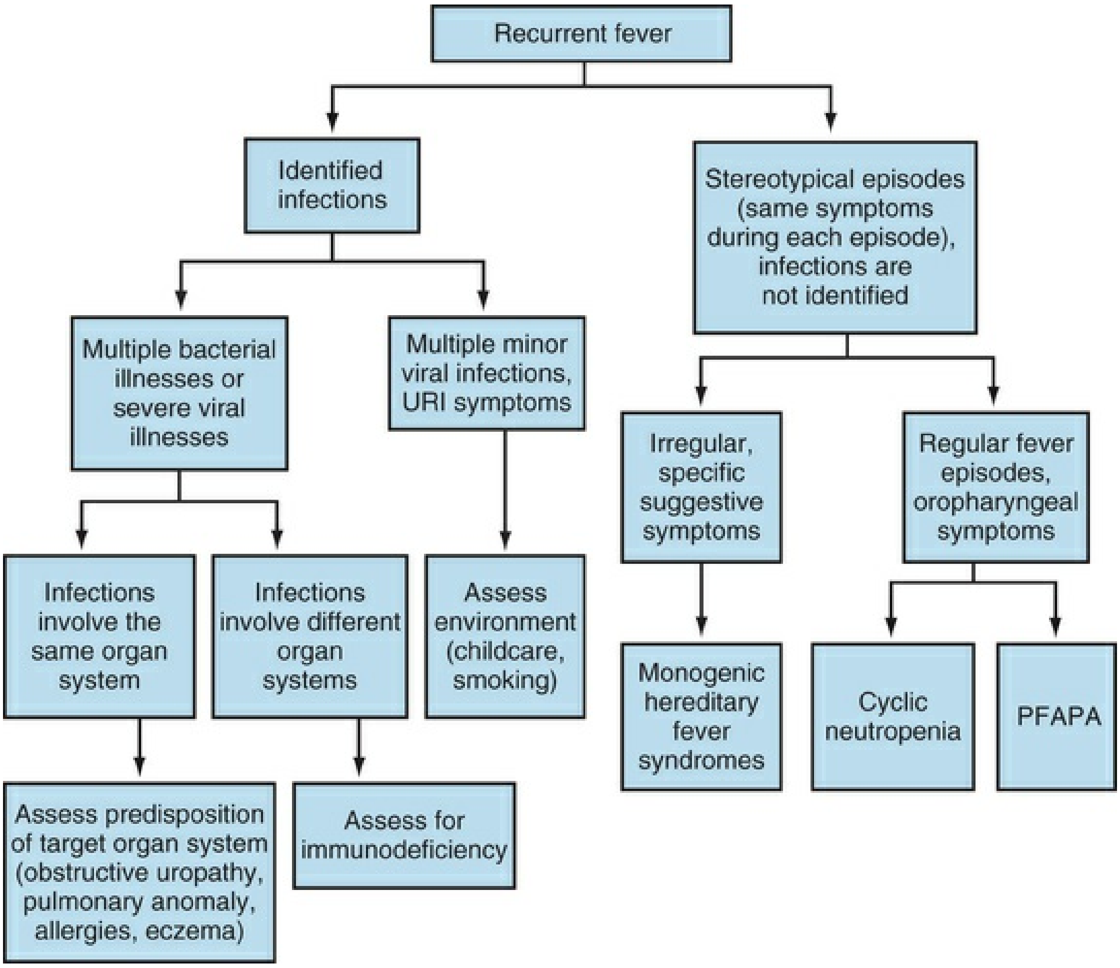
- Set the pace of reconditioning and monitoring.
- Continue to perform examination to ensure normal findings.

Recurrent Fever and Periodic Fever Syndromes

Recurrent Fever

When a history is carefully obtained, most children who are referred to subspecialists for recurrent fever have multiple self-limited infections. Healthy children 2 to 3 years of age can have up to 10 self-limited illnesses per year, and children who attend childcare can have more.

In the absence of respiratory tract symptoms, fever that abates repeatedly during antibiotic therapy occasionally can result from endocarditis, renal infection, central nervous system ventricular shunt infection, or pneumonia in predisposed hosts. Relapsing infections such as *Borrelia recurrentis, Brucella,* and malaria are unusual or rare causes of recurring fevers distinguished by their unique exposures.[74] Autoimmune disorders and certain autoinflammatory disorders with prominent adaptive immune involvement (e.g., inflammatory bowel disease, systemic-onset juvenile rheumatoid arthritis) can also manifest with recurrent fever.[75] Fig. 15.2 shows an approach to analyzing patients with recurrent fever.



Recurrent fever
Identified infections
Stereotypical episodes (same symptoms during each episode), infections are not identified
Multiple bacterial illnesses or severe viral illnesses
Multiple minor viral infections, URI symptoms
Irregular, specific suggestive symptoms
Regular fever episodes, oropharyngeal symptoms
Infections involve the same organ system
Infections involve different organ systems
Assess environment (childcare, smoking)
Monogenic hereditary fever syndromes
Cyclic neutropenia
PFAPA
Assess predisposition of target organ system (obstructive uropathy, pulmonary anomaly, allergies, eczema)
Assess for immunodeficiency

FIGURE 15.2 Approach to recurrent fever. *PFAPA*, Periodic fever, aphthous stomatitis, pharyngitis, and cervical adenitis; *URI*, upper respiratory tract infection. (Data from Long SS. Distinguishing among prolonged, recurrent, and periodic fever syndromes: approach of a pediatric infectious disease subspecialist. Pediatr Clin North Am 2005;52:811–835; Marshall GS. Prolonged and recurrent fevers in children. J Infect 2014;68:S83–S93.)

Periodic Fever

Periodic fever refers to recurring episodes of illness in which fever is the cardinal feature, episodes have a predictable symptom complex and duration, and episodes are separated by symptom-free intervals. Some syndromes are characterized by clockwork periodicity (i.e., multiple recurrences with the same episode duration and same interval between episodes), whereas others have irregular episode timing. Features of several periodic fever syndromes are shown in Table 15.3. Those with identified causative gene mutations are called *hereditary periodic fever syndromes*.

TABLE 15.3

Differentiating Features of Periodic Fever Syndromes

Feature	**PFAPA**	**Cyclic Neutropenia**	**FMF**	**MVK Deficiency**	**TRAPS**
OMIM identifier	—	162800	249100	260920	142680

CAPS, Cryopyrin-associated periodic syndrome; FCAS, familial cold autoinflammatory syndrome; FMF, familial Mediterranean fever; G-CSF, granulocyte colony-stimulating factor; Ig, immunoglobulin; IL-1, interleukin-1; MVK, mevalonate kinase; MWS, Muckle-Wells syndrome; NOMID, neonatal-onset multisystemic inflammatory disease syndrome; OMIM, Online Mendelian Inheritance in Man database; PFAPA, periodic fever, aphthous stomatitis, pharyngitis, and cervical adenitis; TNF, tumor necrosis factor; TNFR1, tumor necrosis factor-α receptor 1; TRAPS, tumor necrosis factor receptor–associated periodic fever syndrome.

The term *autoinflammatory syndrome* was used in the late 1990s to describe a group of systemic inflammatory diseases distinct from infectious, autoimmune, allergic, and immunodeficiency-associated diseases.[76,77] Unlike autoimmune disorders that involve adaptive immune pathways (i.e., development of autoantibodies and activation of T lymphocytes), autoinflammatory diseases result from dysregulation of innate immune signaling. Patients have seemingly unprovoked episodes of systemic or localized inflammation. In addition to the hereditary periodic fever syndromes, Crohn disease; chronic, recurrent, multifocal osteomyelitis; and Behçet disease are considered autoinflammatory diseases,[78] and some also include periodic fever, aphthous stomatitis, pharyngitis, and cervical adenitis (PFAPA) syndrome.[75]

Autoinflammatory conditions known to result from gene mutations are registered in the Online Mendelian Inheritance in Man (OMIM) database (http://www.ncbi.nlm.nih.gov/sites/entrez?db=OMIM).[79] Diagnostic genetic testing for hereditary autoinflammatory diseases is available commercially (http://www.genedx.com or http://www.aruplab.com). Sequence variants involved in hereditary fever syndromes are collected in the

Infevers database (http://fmf.igh.cnrs.fr/infevers),[80,81] which was established in 2002 and expanded in 2009 to an international Eurofever Registry (http://www.printo.it/eurofever/) that includes 67 centers in 31 countries.

In a European study of 228 patients with a history of periodic fever, genetic screening was performed to detect mutations in *MVK, TNFRSF1A,* and *MEFV* genes.[82] The diagnostic Gaslini score was developed by comparing clinical features of mutation-positive and -negative patients. The Gaslini score can be calculated using an online tool (https://www.printo.it/periodicfever/index.asp). Younger age at onset, family history of periodic fever, abdominal pain, thoracic pain, diarrhea, and lack of aphthous stomatitis were significantly associated with identification of gene defects and are used in the Gaslini score.[82]

Clinical syndromic classification is useful (see Table 15.3). PFAPA is by far the most commonly encountered periodic fever syndrome. The likelihood of seeing a patient with a hereditary periodic fever syndrome among those with presumed PFAPA is small (<5% in practice) but can be higher depending on the patient population served and referral patterns.[83–86] In an Italian study of 210 children who met the diagnostic criteria for PFAPA syndrome, 43 children had diagnostic mutations (*MVK,* 33; *TNFRSFIA,* 3; *MEFV,* 7).[87] Mutation-positive patients had a significantly higher frequency of abdominal pain, vomiting, diarrhea, rash, and arthralgia, whereas mutation-negative patients had higher rates of exudative pharyngitis.[87] In this population, the Gaslini score correctly identified 91% of patients with a mutation.

We perform genetic testing for hereditary autoinflammatory diseases for any of the following: onset in patients younger than 6 months or older than10 years of age, prolonged episode duration (>7 days), highly irregular episode timing and durations, positive family history for recurrent fever, migratory rash, arthritis, prominent arthralgia, prominent abdominal pain, or substantial vomiting or diarrhea with episodes. We evaluate for cyclic neutropenia with serial complete blood cell counts or genetic testing in patients with suggestive clinical clues (e.g., gingivitis, minor recurring infections such as cellulitis or otitis media, invasive infections) or laboratory clues (e.g., low absolute neutrophil count during an episode). Because hereditary autoinflammatory diseases have symptom complexes that evolve with age, continued follow-up of children with a diagnosis of PFAPA is important.

The goals of diagnosing hereditary periodic fever syndromes are to intervene to relieve symptoms and to prevent amyloidosis and renal failure. These complications are not seen with PFAPA.

In addition to the periodic fever syndromes discussed in this chapter, several other hereditary autoinflammatory syndromes have been described. Some have significant bone and joint involvement, including pyogenic arthritis, pyoderma gangrenosum and acne (PAPA) syndrome, Majeed syndrome, and deficiency of the interleukin-1β (IL-1β) receptor antagonist (DIRA). Many patients with periodic fever do not conform phenotypically to described syndromes and do not have identified causal mutations.[75]

Periodic Fever, Aphthous Stomatitis, Pharyngitis, and Cervical Adenitis

Epidemiology and Cardinal Clinical Features

PFAPA was first described in 1987 in 12 children from Tennessee and Alabama.[83] More than 700 cases from many continents and racial backgrounds have been reported; undoubtedly, exponentially more cases go unreported or undiagnosed. PFAPA is the most common periodic fever syndrome in children.[21] Between 6% and 10% of patients report a family history of PFAPA,[84,88] but the family history of recurrent fevers or PFAPA-like illnesses can be as high as 45% to 60%.[89,90]

The numerous reported familial cases suggest that affected patients may have predisposing genetic factors.[91–94] Studies investigating polymorphisms in inflammasome-related genes have been small and have not shown a consistently higher prevalence of polymorphisms in affected individuals.[89,95,96] However, PFAPA patients with mutations in *MEFV* have shorter episode duration and more irregularity in episode timing compared with those without the mutations.[97,98] During flares, patients with PFAPA have heightened expression of complement, IL-1β– and IL-18–related genes, and interferon-induced genes compared with asymptomatic periods in PFAPA patients and healthy controls.[89,99] Multiple studies attempting to identify a causative infectious pathogen in

PFAPA have had negative results.

The original diagnostic criteria for PFAPA included five features: regularly recurring fevers (>38.3°C), usually with an early age of onset; constitutional symptoms in the absence of upper respiratory tract infection with at least one symptom being aphthous stomatitis, cervical adenitis, or pharyngitis; exclusion of cyclic neutropenia and other intermittent fever syndromes on the basis of history or laboratory test results; asymptomatic intervals between episodes; and normal growth and development.

Table 15.4 shows features of PFAPA patients followed through a Nashville registry.[84] There are no recognizable triggers for episodes, but many patients have fatigue or irritability a few hours before fever onset. Abrupt onset of fever greater than 39°C, which persists at that level for most of the duration of the episode, is a cardinal feature. Respiratory symptoms are absent. Typically, mouth ulcers are small, shallow, scattered or solitary, and frequently noticed in episodes only after questioning. Pharyngitis usually includes tonsils that are moderately enlarged and erythematous and sometimes have exudate.[85,87,100] Cervical lymph nodes are tender and increase in size bilaterally with episodes but are not erythematous or larger than 3 to 4 cm. Patients frequently also have myalgia, arthralgia, abdominal pain, and headache during episodes.[84,101]

TABLE 15.4

Characteristics at Diagnosis of Periodic Fever, Aphthous Stomatitis, Pharyngitis, and Cervical Adenopathy

Demographic and Clinical Features	**Mean (Range)**	**Signs and Symptoms During Episodes**[a]	**Percentage of Patients**
Male-to-female ratio	1.2	Fever + >1 cardinal feature	97
Onset of PFAPA	2.8 years (2.4–3.3 years)[b]	Cervical lymphadenopathy	77
Maximum temperatures	40.5°C (40.4–40.6°C)	Aphthous stomatitis	67
Duration of fever	3.8 days (3.5–4.1 days)	Pharyngitis	65
Duration of episode	4.8 days (4.5–5.1 days)	Chills	80
Episodes/year	11.5 (10.5–12.5)	Headache	65
Wellness interval	28.2 days (26.0–30.4 days)	Nausea	52
Mean white blood cell count at episode	13,000/mm^3 (2–37 × 10^3)	Abdominal pain	45
Mean erythrocyte	41 mm/hour (5–190	Diarrhea	30

sedimentation rate at episode	mm/hour)		
		Coryza	18
		Rash	15

[a]Although 94 children were included in the original registry, parents did not always answer all queries (frequently citing inability to assess because of age).

[b]Mean (95% confidence interval).

PFAPA, Periodic fever, aphthous stomatitis, pharyngitis, and cervical adenopathy.

Modified from Thomas KT, Feder HM, Lawton AR, et al. Periodic fever syndrome in children. J Pediatr 1999;135:15–21.

Clockwork periodicity of episodes is typical of the syndrome. However, alternating periods of remission and relapses have been seen in some patients, and the natural history of the disease is that episode frequency declines over time.[88,102] Descriptions of the syndrome are similar across countries and have not changed over 2 decades.[83,88,103–105]

Absent or minimal response to acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs), or antibiotics is typical of PFAPA. One or two doses of a corticosteroid abruptly abort an episode. This response sometimes is used as a diagnostic test, but it must be interpreted in the context of the patient's clinical features because patients with mevalonic kinase deficiency (formerly hyperimmunoglobulinemia D syndrome), tumor necrosis factor receptor–associated periodic fever syndrome (TRAPS), and many infectious diseases can have similar responses to corticosteroids.[106] Children with PFAPA are completely well and fully energetic between episodes and grow and gain milestones normally.

Episodes usually begin at 2 to 3 years of age.[83,103] However, 10% of patients have episode onset after 5 years of age.[101] In Israel, 14 adults were reported to have PFAPA-like conditions starting in adolescence or early adulthood; all responded to a single dose of prednisone.[107]

Treatment and Outcome

The longest follow-up study of PFAPA reported the outcomes of 60 children followed for 12 to 21 years.[88] In this study, 85% had complete resolution of PFAPA episodes (mean duration, 6.3 years). Lengthening of the intervals between fevers frequently preceded resolution of PFAPA in these patients. The remainder (15%) continued to have persistent PFAPA episodes for a mean duration of 18 years (range, 14 to 25 years). In those with persistent fever, the duration of fever declined from 3.6 to 1.8 days and symptom-free intervals increased from 29 to 159 days over time.

Patients with PFAPA usually do not develop other diagnoses or long-term serious consequences of the illness. Of the 60 patients described, 1 patient was diagnosed with Behçet disease and another with familial Mediterranean fever.[88] More than one-third of patients had recurrent aphthous stomatitis, often after cessation of fever episodes. With time, episodes of PFAPA typically retain the same symptoms as at diagnosis. Families should be questioned at follow-up about development of additional features. If they are reported, the diagnosis should be reconsidered.

When given daily as prophylaxis, cimetidine therapy is associated with resolution or amelioration of fever attacks in approximately one-third of patients.[84] Prednisone can be given in a dose of 1 to 2 mg/kg and characteristically aborts an attack of PFAPA within 2 to 12 hours[84,88,103]; 18% of patients may need a second dose.[103] In a single medical center's experience, a lower dose of prednisone (mean, 0.6 mg/kg per day) also was effective.[102] Corticosteroid use may lead to increased frequency of episodes in 7% to 50% of patients,[84,88,102,103] and frequent, repeated use can have detrimental side effects.

Tonsillectomy was first found to be curative in patients with PFAPA in 1989.[108] In a 2011 systematic review of tonsillectomy for PFAPA, 15 studies were identified involving a total of 149 children.[109] Thirteen of the studies were observational and noncomparative, and two were prospective, randomized, controlled trials (RCTs).[110,111] Comparisons of these studies were limited by variations in diagnostic criteria for PFAPA, type of surgical procedure performed (i.e., tonsillectomy with or without adenoidectomy), and duration of follow-up. For all studies combined, 83% (95% confidence interval [CI], 77%–89%) of patients had resolution of episodes after surgery. The odds ratio for complete resolution after surgery in the two RCTs was 13 (95% CI, 4–43).[109] Another study from a single U.S. center reported that 99 of 102 patients who underwent tonsillectomy for PFAPA had complete resolution of fever episodes when followed for an average of 43 months.[112]

Anakinra and colchicine have been used in patients with PFAPA.

In an Israeli study, 9 patients with frequent episodes (≤14 days apart) were given daily colchicine prophylaxis. The patients had an increase in the average interval between episodes (1.7 to 8.4 weeks).[113] Anakinra, an IL-1β receptor antagonist, was shown in a small group of patients to abort fever episodes, but some patients needed multiple doses during each episode to achieve fever control.[99]

We discuss these options with parents at the time of diagnosis, assess with them the degree to which the episodes interfere with the child's and family's quality of life, recommend commencement of a diary to accrue a history of episodes, and attempt medical management before a surgical decision is made. With this approach, some patients do not have PFAPA-fulfilling courses, many families are comfortable with following the natural history, and a few evolve to symptoms of a hereditary autoinflammatory disease.

Cyclic Neutropenia

Epidemiology and Etiology

Cyclic neutropenia is an autosomal dominantly inherited hematologic disorder, not an autoinflammatory disorder, characterized by regular cycling of the peripheral blood neutrophil count to a nadir of less than 500 cells/mm^3 (usually <200 cells/mm^3) and a symptom complex manifesting during the neutrophil nadir. Most patients with cyclic neutropenia have mutations in the *ELANE* gene (formerly called *ELA2)*, which encodes neutrophil elastase. Many patients with severe congenital neutropenia also have mutations in *ELANE.*[114,115] In some cases, particular mutations are associated with cyclic neutropenia, but others are associated with congenital neutropenia; however, individuals with both disorders have been reported to have the same mutation.[116] The favored hypothesis is that mutations in neutrophil elastase (i.e., protease) lead to destabilization of a proteoglycan, which induces unfolding and increases the transcription of endoplasmic reticulum–associated protein degradation and proapoptotic genes that ultimately lead to neutrophil apoptosis in bone marrow.[117]

Cardinal Clinical Features

The diagnosis of cyclic neutropenia usually is established in infancy.[118] Cardinal features are recurrent fever with clockwork periodicity (typically a 21-day cycle), pharyngitis, mouth ulcers, and lymphadenopathy. Untreated individuals often have oropharyngeal inflammation, including gingivitis, periodontitis, and tooth abscesses, which often persist into the second week after a fever episode. Periodontal disease can lead to deciduous tooth loss in childhood. Mouth ulcers are deep and painful. Recurrent bacterial infections, such as cellulitis (especially at sites of minor trauma), otitis media, sinusitis, and pharyngitis, differentiate cyclic neutropenia from the periodic autoinflammatory syndromes. Some patients have few or relatively minor bacterial infections, whereas others can have spontaneous bacterial peritonitis, overwhelming gram-negative or *Clostridium* septicemia, or septic shock resulting from ileocolonic ulceration during neutropenic episodes. Although oral manifestations may linger, these children usually are well between episodes.

During the neutropenic period, peripheral blood neutrophils characteristically fall to less than 200 cells/mm^3 for 3 to 7 days.[119] The absolute neutrophil count then rises and remains at approximately 2000 cells/mm^3. At the time that clinical symptoms of fever appear, neutropenia may be resolving, typically with immature myelocytic cells found in peripheral blood. Monocyte counts may cycle in the opposite direction of neutrophils. Children with clockwork periodicity of fevers plus any familial or clinical features (as previously described) compatible with cyclic neutropenia should have complete blood cell counts performed two or three times weekly during the interval of wellness and continuing through the next febrile episode. Alternatively or additionally, genetic testing for *ELANE* mutations can be performed. Although the inheritance pattern is autosomal dominant, manifestations can be mild, and parental inheritance may be unrecognized. Severity of symptoms declines with age.[119]

Course, Treatment, and Outcome

Granulocyte colony-stimulating factor (G-CSF) administered subcutaneously daily is effective treatment for cyclic neutropenia. G-CSF is thought to affect intracellular signaling and stimulate neutrophil production. Doses are titrated to achieve an absolute neutrophil count of 1500 cells/mm or higher.[115]

Familial Mediterranean Fever

Epidemiology and Etiology

Familial Mediterranean fever (FMF) is the most common hereditary periodic fever syndrome. In 1997, mutations in a single gene *(MEFV)* on the short arm of chromosome 16 were implicated as the cause of FMF.[120,121] *MEFV* encodes a protein product called *pyrin* (from the Greek *pyrus* ["fever"]). Pyrin is a member of the death domain superfamily, which is part of critical pathways of apoptosis and innate immunity. There is general consensus that through complex intracellular mechanisms, pyrin plays a role in modulating caspase 1 activity and subsequent IL-1β release.[122] Particular ethnic groups, including Sephardic and Ashkenazi Jewish, Middle Eastern Arab, Armenian, Italian, North African, and Turkish populations, have a high carrier frequency of MEFV mutations (up to one in three people).[123] FMF is more prevalent but not exclusively found in these populations.

More than 50 disease-associated mutations have been identified, and most are nucleotide substitutions in exon 10. FMF is considered to have autosomal recessive inheritance, but in an Israeli population, as many as 30% of patients with clinical symptoms of FMF were heterozygous for *MEFV* mutations, and 28% had no mutation in *MEFV*.[124] M694V is the most commonly identified mutation and is associated with young age at episode onset, a severe course, and a high risk of amyloidosis.[124] Other common pathogenic mutations include M694I, M680I, and V726A.

Cardinal Clinical Features

FMF flares are characterized by short episode duration (lasting 12 to 72 hours) and typical painful symptoms, including serositis involving the synovia, pleura, or peritoneum. Approximately 90% of patients have recurring abdominal pain, and 40% have thoracic pain.[125] Many patients have an erysipelas-like rash. Disease onset occurs before 10 years of age in 25% to 60% of cases and before 20 years of age in 64% to 90% of cases. The mean delay in diagnosis is 7 years.[125]

Episodes typically do not have clockwork periodicity with weeks to years between episodes and can be triggered by stress or minor trauma. Abdominal pain (i.e., sterile peritonitis) ranges from mild and localized to severe and diffuse with abdominal rigidity, which may be mistaken for appendicitis. Well-demarcated erysipelas-like lesions are distinctly associated with FMF and typically develop bilaterally or unilaterally below the knees anterior to the dorsum of the feet.[126] Histologic examination reveals dermal infiltration of neutrophils. Children also may exhibit purpuric lesions of the face, trunk, and extremities.[127] Arthritis usually is monoarticular, involving the knee, ankles, or hips; synovial fluid pleocytosis is neutrophilic. Children are well between episodes.

Course, Treatment, and Outcome

The most serious complication of FMF is amyloidosis. Serum amyloid A is an acute phase reactant that can deposit in many organs, including the kidney, leading to organ failure. Before colchicine therapy, end-stage renal disease occurred in many FMF patients by the age of 40 years. Oral colchicine is the treatment of choice for children and adults, reducing the frequency and severity of attacks and the risk of amyloidosis.[128]

Pyrin interacts with tubulin and colocalizes with microtubules, suggesting a rationale for the high efficacy of colchicine, a microtubular-destabilizing agent.[129] In those who cannot tolerate colchicine, IL-1β blockade with anakinra, an IL-1β receptor antagonist; canakinumab, and anti–IL-1β monoclonal antibody; or rilonacept, a fusion protein targeting IL-1β has been beneficial.[130]

Mevalonate Kinase Deficiency

Epidemiology and Etiology

Hyperimmunoglobinemia D and periodic fever syndrome (HIDS) was first described in several Dutch patients in 1984.[131] In 1999, the causative *MVK* gene was localized on the long arm of chromosome 12.[132,133] *MVK* encodes the enzyme mevalonate kinase (MVK), and MVK deficiency is a more accurate name for the condition; additionally, not all patients have elevated levels of IgD. The HIDS registry in the Netherlands has data on more than 200 patients worldwide. Although most patients are from northern Europe, some have been from the Mediterranean basin and Asia.[125]

MVK deficiency is an autosomal recessively inherited disorder. More than 35 pathogenic mutations have been reported. Most patients are compound heterozygotes for missense mutations, resulting in residual *MVK* activity that is 1% to 8% of normal. Mutations in *MVK* also are responsible for mevalonic aciduria, in which mutations cluster around the active sites of the enzyme and result in total absence of enzyme activity and a catastrophic disease characterized by dysmorphic features, failure to thrive, mental retardation, ataxia, recurrent fever attacks, and death in early childhood. Rare patients with MVK deficiency have neurologic signs, suggesting that these may be overlapping syndromes.[134]

MVK is an essential enzyme in the isoprenoid biosynthesis pathway and cholesterol cascade. The pathogenic mechanisms leading to autoinflammatory disease are not well understood. Lack of isoprenoids, which are metabolic products downstream from MVK, rather than an excess of mevalonate leads to caspase 1 activation, which cleaves pro–IL-1β to its active form.[135] Stimuli such as infection or vaccination that activate the inflammasome to produce pro–IL-1β also trigger episodes.

Cardinal Clinical Features

Clinical features and longterm follow-up of 103 patients from 18 different countries from the HIDS registry have been reported.[136] The median age of the first attack was 6 months (range, 0–120 months), and almost 70% of patients had their first attack before the age of 12 months. The median time from disease onset to diagnosis was 9.9 years.

A typical attack starts with prodromal symptoms such as malaise and headache, followed by a rapid rise in temperature (often >40°C), chills, enlargement of and pain in cervical lymph nodes, abdominal pain, vomiting diarrhea, and arthralgia of large peripheral joints (with arthritis in 50%). Skin lesions occur during attacks in more than two-thirds of patients. Although small macules, papules, and nodules are the usual exanthem, urticaria, purpura, and erythema nodosum have been reported.[126,137] Histology of lesions ranges from mild vasculitis to dense dermal infiltrate of neutrophils.[127] Oral aphthous ulcers with or without genital ulcers are reported in almost one-half of patients.[136] One-third to one-half of patients have splenomegaly during attacks.[127,136]

In the HIDS registry, childhood vaccinations induced the first attack in two-thirds of patients.[125] Injury, physical exercise, or emotional stress can also trigger attacks.[127] MVK deficiency and PFAPA have similar episode frequency and duration, and patients are well between episodes. Differentiating features of MVK deficiency, such as severe headache, gastrointestinal complaints, rash, genital ulceration, and arthralgia, can evolve years after the onset of febrile episodes. Almost one-fourth of patients with MVK deficiency report decreases in episode duration and severity in response to brief corticosteroid use, making differentiation from infections or PFAPA problematic.[136]

Although the original disease name suggests that patients have elevated serum IgD levels, 22% of patients have normal IgD levels,[136] especially children younger than 3 years of age.[138] Most patients with elevated IgD levels and no *MVK* mutation have no definite diagnosis.[139] Elevated IgA levels have been reported for 64% of MVK-deficient patients.[140] Mevalonic acid concentrations in urine are elevated during febrile episodes, but testing is not readily available. Genetic testing for *MVK* mutations is the best confirmatory test, and V377I and I268T are the most commonly identified mutations. However, some patients with typical symptoms are heterozygotes with only one identified mutation.

Course, Treatment, and Outcome

Patients have decreasing frequency of attacks with age; 44% had more than 12 attacks per year in their first decade of life, 30% in their second decade, and 18% in their 20s.[136] Amyloidosis occurred in 3 (3%) of 103 patients in the HIDS registry, and all of these patients had episodes for more than 20 years before manifesting amyloidosis. Abdominal adhesions and joint contractures also were reported.

Statin therapy has had mixed results. In the Eurofever registry, NSAIDs were frequently used, with 64% of patients having partial responses and 13% having complete responses.[130,141] Corticosteroids reduced the severity and duration of episodes (i.e., 24% had complete responses, and 67% had partial responses).[141] Anakinra resulted in at least partial remission in 89% of patients, whereas etanercept, a tumor necrosis factor-α (TNF-α) receptor fusion protein, was efficacious in 65% of patients.[141]

Tumor Necrosis Factor Receptor–Associated Periodic Fever Syndrome

Epidemiology and Etiology

In 1982, a large Irish family with recurrent episodes of fever, myalgia and rash was described and this fever syndrome was called familial Hibernian fever.[142] This syndrome is now referred to as tumor necrosis factor receptor–associated periodic fever syndrome (TRAPS). Since the original description, cases have been reported in a wide range of ethnic groups, including people of African American, Mexican, Mediterranean, and European origin.[143] TRAPS is an autosomal dominant disease with variable penetrance.

In 1998, linkage studies placed the susceptibility locus in chromosome 12,[76,144] and within a year, mutations in the *TNFRSF1A* gene were determined to be causative.[145] The exact pathophysiology of TRAPS remains unclear. *TNFRSF1A* encodes the TNF-α receptor 1 protein (TNFR1). TNF-α binds and stimulates TNFR1, which recruits several proteins to form a complex that ultimately activates nuclear factor-κB (NF-κB) and the apoptosis pathway. Some mutations in TNFR1 impair metalloprotease cleavage of the receptor, leading to defective shedding at the cell surface. The soluble receptor acts as a decoy for TNF-α, and lack of receptor shedding in TRAPS leads to proinflammatory signals. In other patients, the mutant TNFR1 is unable to traffic appropriately from the endoplasmic reticulum to the cell surface. Mutant TNFR1 also may result in prolonged survival of inflammatory cells through impaired TNF-mediated apoptosis.[146]

Cardinal Clinical Features

TRAPS is characterized by recurrent attacks of fever, migratory myalgia, tender erythematous plaques, abdominal pain, and periorbital edema or other ocular complaints due to conjunctivitis, uveitis, or iritis.[75,143] Chest pain due to pleuritis or pericarditis and mouth ulcers occur in less than 20% of patients. Ocular manifestations and migrating myalgias are distinguishing features of TRAPS.[143] Disease manifestations also can be milder and vary among family members.

Almost two-thirds of patients develop distinctive cutaneous lesions of localized erythematous macules or patches.[126,137] Lesions appear to undergo a set progression from solitary or grouped macules and papules to lesions that expand and coalesce, resulting in annular and serpiginous patches and plaques that migrate distally. Skin lesions overlie areas of myalgia.[127,137] A third of cutaneous lesions resolve with an ecchymotic appearance. Microscopy of skin lesions reveals superficial and deep perivascular infiltrates of lymphocytes and monocytes.[127]

Compared with other periodic fever syndromes, TRAPS flares are longer, typically lasting 7 to 21 days. Injury, immunizations, and stress can trigger episodes. In one study, the mean age at onset was 18 months for severe TRAPS and 58 months for mild TRAPS.[147]

Course, Treatment, and Outcome

The most severe complication of TRAPS is amyloidosis, occurring in 8% to 10% of patients.[127,143] In the Eurofever registry, etanercept, which binds serum TNF-α and prevents its engagement with the cell surface TNFR1, had some benefit in 86% patients, but only 30% had complete remission, and the response can decrease with time.[141,146] Anakinra produced complete remission in 79% of patients, which supports its increasing use as a first-line agent.[141,147,148] For some patients, treatment with infliximab, which is a monoclonal antibody that binds TNF-α, led to worsening of symptoms.[149]

Cryopyrin-Associated Periodic Syndrome

Epidemiology and Etiology

Cryopyrin-associated periodic syndrome (CAPS) includes three disorders: familial cold autoinflammatory syndrome (FCAS), previously called familial cold urticarial (FCU) syndrome; Muckle-Wells syndrome (MWS); and neonatal-onset multisystemic inflammatory disease syndrome (NOMID), also known as chronic infantile neurologic, cutaneous, and articular (CINCA) syndrome. These three syndromes represent a spectrum of disorders that share characteristics of episodic fever, urticaria-like rash, and joint involvement. FCAS is considered the mildest, MWS is intermediary, and NOMID is the most severe.[127,146,150] These syndromes have autosomal dominant inheritance patterns, but many de novo cases have been reported, particularly of NOMID.[151] Although most reported cases are from the United States and Europe (predominantly northern Europe), patients from other regions, including the Mediterranean, have been described.[152]

Linkage studies placed the susceptibility locus for MWS and FCAS on chromosome 1, and mutations were identified in the cold-induced autoinflammatory syndrome 1 gene (*CIAS1)*, which is now designated as *NLRP3*.[153–155] In 2002, mutations in the same gene were identified in NOMID.[151,156] *NLRP3* encodes the protein cryopyrin, which is part of a macromolecular complex called the inflammasome.[146] Inflammasome assembly leads to activation of caspase 1, which cleaves pro–IL-1β into its bioactive form. Patients with CAPS have a gain of function mutation in cryopyrin, leading to constitutive inflammasome activation. More than 50 missense mutations in *NLRP3* have been identified in patients with CAPS; some are unique to particular disorders, and others are found in several disorders. Of 18 U.S. patients with the clinical diagnosis of NOMID, 40% did not have *NLRP3* mutations despite having indistinguishable phenotypes from those with mutations.[156]

Cardinal Clinical Features

CAPS episodes are characterized by fever, urticaria-like rash, and joint pain. Onset of CAPS usually occurs in the first 6 months of life.

FCAS episodes are induced by generalized exposures to cold temperatures but not necessarily by contact with cold objects or drinking cold liquids.[75] Symptoms often are delayed an average of 2.5 hours after exposure and last approximately 12 hours.

MWS is not necessarily triggered by changes in temperature and episodes last longer (1–days). Microscopic examination of skin lesions reveals perivascular infiltrate of neutrophils without vasculitis, mast cells, or mast cell degranulation.[127] Lesions usually are not pruritic. Systemic symptoms of fever, headache, nausea, sweating, drowsiness, extreme thirst, conjunctivitis, blurred vision, ocular pain, and polyarthralgia can occur during episodes. Patients with MWS often have progressive sensorineural hearing loss in childhood.

NOMID manifests within the first 6 weeks of life with fever, urticaria-like rash, chronic arthritis, and a characteristic bony overgrowth predominantly involving the knees.[157] Central nervous system manifestations include chronic aseptic meningitis, increased intracranial pressure, cerebral atrophy, ventriculomegaly, chronic papilledema, optic atrophy and loss of vision, mental retardation, seizures, and sensorineural hearing loss.

Course, Treatment, and Outcome

Patients with FCAS have normal lifespan, but 20% of those with NOMID die before adulthood.[157] Amyloidosis occurs in a substantial percentage of patients with CAPS.

Corticosteroids can alleviate symptoms but not disease progression. IL-1β inhibition agents have been successful in treating all three syndromes. In a study of 18 patients with NOMID, anakinra therapy resulted in complete remission of central nervous system inflammation in most patients. Discontinuation of therapy resulted in rapid relapse, and reintroduction produced remission.[157] All 14 patients in an Italian registry of CAPS had significant and persistent improvement in clinical manifestations and quality of life with anakinra.[158] In a randomized, placebo-controlled trial, 15 patients who received canakinumab had complete remission compared with 19% of those receiving placebo.[159]

Lymphatic System and Generalized Lymphadenopathy

Mary Anne Jackson, J. Christopher Day

Anatomy and Function of Lymphoid Tissue

The lymphoid system is composed of an extensive capillary network that drains lymph into elaborate systems of collecting vessels. The collecting vessels merge and empty lymph into the bloodstream by way of the thoracic duct at its entry into the left subclavian vein or by the right lymphatic duct, which empties into the right subclavian vein. Specialized lymphatic structures interspersed along the collecting vessels include the tonsillar tissues of the Waldeyer ring, the thymus, the spleen, mucosa-associated lymphoid nodules, and lymph nodes (Table 16.1).

TABLE 16.1

Anatomic Types of Lymphoid Tissue

Type of Tissue	Location	Distinguishing Features
Discrete lymph	Occipital, preauricular, postauricular, submandibular, submental, facial,	Nodes have discrete capsules; afferent lymphatic flow enters from periphery;

node groups	parotid, cervical, supraclavicular, para-aortic, axillary, epitrochlear, inguinal, iliac, popliteal, mediastinal, hilar, pelvic, mesenteric, celiac	efferent lymphatic flow exits and blood vessels enter and exit through hilum of node
Waldeyer ring	Pharyngeal (adenoid), palatine (faucial), lingual and tubal (Gerlach) tonsils; lateral pharyngeal bands; posterior pharyngeal granulations	Aggregates of lymphoid nodules are partially encapsulated; no afferent lymphatics and no lymphoid sinuses; efferent lymphatic flow is not as structured as for lymph nodes
Lymphoid nodules	Small, submucosal lymphoid collections throughout the intestinal (i.e., Peyer patches), respiratory, and genitourinary tracts (i.e., mucosa-associated lymphoid tissue [MALT])	Lymphatic flow is not encapsulated or structured; tissue responds to mucosal antigens with phagocytosis and immunoglobulin A production
Thymus	Anterior mediastinum	Organ is composed of lymphoid and epithelial cells; no afferent lymphatic vessels; protected from antigen; essential for development and maturation of peripheral lymphoid tissues
Spleen	Abdomen	Lymphatic tissue is uniquely specialized to filter blood; largest lymphatic organ in the body; no afferent lymphatic vessels and no lymphatic vessels within spleen; sinusoid structure is similar to lymph node but lymph empties into splenic vein

The Waldeyer ring of lymphoid tissue that surrounds the oropharyngeal isthmus and the opening of the nasopharynx into the oropharynx is uniquely positioned to interact with foreign material entering the nose or mouth. The ring is formed superiorly by the midline pharyngeal (adenoid) tonsil, which is located in the roof of the nasopharynx, and inferiorly by the lingual tonsils in the posterior third of the tongue. On either side of the pharynx, the lateral pharyngeal bands of lymphoid tissue connect the adenoid to the tubal tonsils of Gerlach at the openings of the eustachian tubes and to the faucial (palatine) tonsils. Smaller aggregates of lymphoid tissue in this area include the posterior pharyngeal granulations and the lymphoid tissue within the laryngeal ventricle.

Small submucosal lymphoid nodules located throughout the respiratory, gastrointestinal, and genitourinary tracts are composed of phagocytic and lymphoid cell collections without a connective tissue capsule. These nodules are ideally situated to respond to mucosal antigens.

The thymus, which is located over the superior vena cava in the anterior mediastinum, is relatively protected from antigens. Surrounded by a thin connective tissue capsule, the thymus is uniquely composed of epithelial and lymphatic elements.

The spleen is the largest lymphatic organ in the body and the only lymphatic tissue specialized to filter blood. Similar to the lymph nodes, the spleen is a component of the peripheral lymphoid system and is composed of red pulp (i.e., red blood cells) and an interior of white pulp, which contains lymphoid nodules with germinal follicles.

Normal lymph nodes are small, oval or bean-shaped bodies that are strategically located along the course of lymphatic vessels to filter lymph on its way to the bloodstream. Lymphatic vessels enter around the periphery of the nodes. Lymph filters through the cortex to the medulla of the node and exits through the hilum. Blood vessels enter and leave through the hilum, which is connected to capillaries that course through the node. During this process, lymphocytes can leave the blood and re-enter the lymphatic circulation.

Nodes are densely packed with lymphocytes that are organized loosely into cortical nodules and medullary cords by connective tissue trabeculae and lymphatic sinuses. The juxtaposition of phagocytic cells, antigen-processing cells, and lymphocytes in an area of sluggish blood flow is ideally suited to provide the first line of defense against pathogens. As lymph slowly filters through the rich reticular network, organisms are trapped and can be ingested by phagocytic cells, stimulating the release of cytokines, which recruits lymphocytes for immunologic responses. The lymph node groups in the body can be divided into the superficial and peripheral nodes, which usually are easily palpable, and the deeper groups adjacent to major vessels and viscera (see Table 16.1).

Developmental Changes

Lymphoid tissue, including the thymus, forms a significantly larger percentage of total body weight in infants and children than in adults. Considerable lymphoid activity is present at birth, and continuing exposure to environmental antigens results in an increase in lymphoid mass that reaches a peak between the ages of 8 and 12 years. Atrophy of lymphoid tissue begins during adolescence. In children, the thymus can weigh 40 g; in adults, the thymus is replaced by fibrous and fatty tissue and can weigh only 10 g. By adult standards, almost all children have lymphadenopathy because palpable nodes, particularly in the cervical, axillary, and inguinal areas, are common in children of all ages, including neonates (Table 16.2). Prominent palatine tonsils are common in preadolescent children, whereas in infants younger than 1 year of age and adults, the palatine tonsils usually are not visible.

TABLE 16.2

Frequency and Location of Palpable Peripheral Lymph Nodes in Healthy Children

Palpable Node	Neonate[a]	Age <2 Years[b]	Age >2 Years[b]
Cervical	+	++	++
Postauricular	−	+	−
Occipital	−	++	+
Submandibular	−	+	++
Supraclavicular	−	−	−
Axillary	+	+++	+++
Epitrochlear	−	−	−
Inguinal	+	+++	+++
Popliteal	−	−	−
None	++	++	++

[a] Data from Bamji M, Stone RK, Kaul A, et al. Palpable lymph nodes in healthy newborns and infants. Pediatrics 1986;78:573.

[b] Data from Herzog LW. Prevalence of lymphadenopathy of the head and neck in infants and children. Clin Pediatr 1983;22:485.

+++, Normally found in less than 50% of children; ++, normally found in 25% to 50%; +, normally found in 5% to 25%; −, normally found in less than 5%.

Because of their normally hyperplastic nodes, the response of children to antigenic, infectious, or neoplastic stimuli is much more rapid, prolific, and exaggerated than that in adults. Lymph nodes can increase in size as much as 15-fold within 5 to 10 days of antigen exposure. Increased size of mediastinal and mesenteric nodes can be particularly pronounced.

Characteristics of Lymphadenopathy

Lymphadenopathy (i.e., enlarged lymph nodes) can be characterized by size, location, consistency, rate of growth, tissue inflammation, and fixation. In all ages and lymph node groups, a node is considered enlarged if it measures (in the longest diameter) greater than 10 mm. There are two exceptions to this rule. In the epitrochlear region, nodes greater than 5 mm are abnormal, and in the inguinal region, only nodes greater than 15 mm are considered abnormal.

Most children examined when healthy have palpable lymph nodes.[1] In healthy neonates, lymph nodes ranging from 3 to 12 mm in the longest diameter can be found in the cervical, axillary, and inguinal regions.[2] In children younger than 2 years, palpable nodes can be found at any peripheral location, except in the epitrochlear, supraclavicular, and popliteal areas, where palpable lymph nodes always are abnormal. In children older than 2 years, palpable lymph nodes in these areas and in the posterior auricular and suboccipital areas are considered abnormal.

Characteristics of lymph nodes are determined by palpation (Table 16.3). Soft, discrete, nontender, small (<2 cm) nodes that are found bilaterally or usually with no periadenitis, cellulitis, or abscess formation typically result from hyperplasia due to viral infection. Unilateral, large (>2 cm), warm, tender, poorly defined nodes with surrounding edema, erythema, or abscess formation usually are infected with pyogenic bacteria. Moderately large, unilateral nodes with discrete margins and minimal inflammation that progress slowly to become erythematous (but not warm), fluctuant, and adherent to overlying skin are characteristic of chronic, usually bacterial infections.

TABLE 16.3

Characteristics of Enlarged Lymph Nodes According to Cause

Characteristic	Causes of Enlargement			
	Acute Bacterial	Chronic Bacterial	Acute Viral	Malignant
Large size	+++	+++	+	++/+++
Erythema	+++	++	−	−
Tenderness	+++	++	+	++
Consistency	Soft or firm	Firm	Soft	Firm or rubbery
Discrete	++	+++	+++	+++
Matted	++	++	−	++
Fixed	+++	+	−	−
Fluctuant	+++	+++	−	−
Associated with cellulitis	+++	+	−	−
Unilateral	+++	+++	−	+

+++, Common finding; ++, less common finding; +, occasional finding; −, rare.

Enlarged nodes resulting from lymphoma usually are firm, discrete, freely movable, nontender, and rubbery, and they have no surrounding inflammation. Nodes increase in size over time, and adjacent nodes can become matted together and lose individual characteristics. Suppuration and fixation to skin or deeper structures, as seen in inflammatory lymphadenopathy, are not expected in lymphoma. Lymphomatous nodes can wax and wane in size over weeks to months, and lymphomatous changes can develop or become more apparent in nodes for which a biopsy specimen initially showed only hyperplasia.[1–3] Enlarged nodes that result from metastatic tumors are hard and bound to each other and to surrounding tissues.

Enlarged nodes can be single or multiple and contiguous. When confined to one region, the condition is referred to as *regional lymphadenopathy*. Enlargement of a single node or regional nodes can be the result of localized disease or the first manifestation of generalized lymphadenopathy. *Generalized lymphadenopathy* is defined as the simultaneous occurrence of two or more enlarged nodes in noncontiguous groups; enlargement need not be identified in every body site. Concurrent mesenteric and hilar adenopathy is considered generalized lymphadenopathy. Splenomegaly also can occur but is not included in the definition.

Pathogenesis of Lymphadenopathy and Lymphadenitis

Microorganisms reach lymph nodes directly by lymphatic flow from the inoculation site or by lymphatic spread from adjacent nodes. If initial involvement of regional nodes does not contain infection adequately, organisms can reach noncontiguous nodes by hematogenous spread. Lymph node enlargement can result from a variety of mechanisms (Box 16.1).

Box 16.1

Mechanisms of Lymph Node Enlargement

Cells within the node replicate in response to antigenic stimuli or as a result of malignant transformation.

Cells exogenous to the node, such as neutrophils or metastatic neoplastic cells, enter the node in large numbers.

Foreign material is deposited within histiocytic cells of the node (e.g., lipid storage diseases).

Local cytokine release leads to vascular engorgement and edema.

Tissue necrosis leads to suppuration.

In acute pyogenic lymphadenitis, the initial inflammatory response in the node, including complement activation and cytokine release, causes recruitment of neutrophils and mononuclear phagocytes. Vascular engorgement, intranodal edema, and cellular replication in response to the antigenic stimulus lead to rapid enlargement of the node. Involvement of adjacent lymph nodes and surrounding soft tissues, including skin, can result in cellulitis, suppuration, necrosis, and fixation to adjacent tissues. After purulence occurs, lymph node architecture and antibiotic access are destroyed. Healing occurs by fibrosis.

For microorganisms that cause subacute or chronic granulomatous changes, the increase in node size and tenderness and adjacent inflammatory response usually are modest. Formation of granulomas and, in some cases, caseating necrosis also destroy nodal architecture; drainage or removal may be required to relieve pain or hasten resolution.

With local or generalized viral infections, the nodal response primarily is one of hyperplasia without necrosis. This resolves as infection abates without sequelae.

Enlarged lymph nodes, lymphoid nodules, or lymphoid tissue such as the Waldeyer ring can result in obstruction, compression, or erosion of important structures, rupture of nodal contents, or inflammation of adjacent structures. Generalized hyperplasia of the Waldeyer ring can result in obstruction of the posterior nares, eustachian tube, or oropharynx. Extensive mediastinal lymphadenopathy can lead to obstruction or erosion of the airways, esophagus, superior vena cava, recurrent laryngeal nerve, or lymphatics (see Table 18.3). Gastrointestinal inflammation of Peyer patches (e.g., *Salmonella* Typhi infection) can lead to intestinal perforation and hemorrhage or serve as the lead point for intussusception. Infectious mesenteric lymphadenitis can lead to an intra-abdominal abscess. Perinodal inflammation of muscles in the neck results in torticollis, and spread of infection in the neck can lead to deep fascial space infections.

Histopathology of Lymphadenitis

Nonspecific hyperplasia is the most common histopathologic finding in biopsy specimens of enlarged lymph nodes. The cause is not determined in most children, and the condition usually resolves. For 17% to 25% of cases, however, a pathologic process ultimately develops, most often a lymphoreticular disease.[3–5]

In acute pyogenic infection, lymph nodes are filled with neutrophils, microorganisms, edema, and necrotic debris. Granuloma formation along with caseating necrosis is typical of infections caused by *Mycobacterium tuberculosis, Histoplasma capsulatum, Coccidioides immitis,* and some nontuberculous mycobacteria. Stellate abscesses surrounded by palisading epithelioid cells are typical for lymphogranuloma venereum (caused by *Chlamydia trachomatis*) and infections caused by *Bartonella henselae* and *Francisella tularensis* (with more extensive granuloma formation in the latter). Toxoplasmosis produces characteristic nodal histologic findings of reactive follicular hyperplasia with scattered clusters of epithelioid histiocytes in cortical and paracortical zones, blurring of margins of germinal centers, and focal distention of subcapsular and trabecular sinuses by monocytoid cells. *Yersinia* spp. can cause necrotizing lymphadenitis in cervical, mediastinal, and mesenteric nodes. Brucellosis is characterized by noncaseating granulomas that are indistinguishable from those of sarcoidosis.

Lymphocutaneous and Oculoglandular Syndrome

For several infections resulting in regional and, with extension, generalized lymphadenopathy, a characteristic and often granulomatous inflammatory reaction develops at the site of inoculation. Regional adenopathy often develops from lymphatic spread of organisms before the inoculation site has healed. When the initial inoculation site is in the conjunctiva, the constellation is the Parinaud oculoglandular syndrome, and when in the skin, it is the lymphocutaneous syndrome. Organisms that cause these syndromes are shown in Box 17.1 in Chapter 17.

Infectious Causes of Generalized Lymphadenopathy

Local or generalized lymph node enlargement due to self-limited conditions must be differentiated from potentially life-threatening disorders such as a neoplasm, histiocytic proliferation, or autoimmune disease.[6,7] The distinctions usually can be made on the basis of history, lymph node examination (see Table 16.3), other systemic manifestations, and a limited number of laboratory tests (Box 16.2).

Box 16.2

Steps in Evaluating the Child With Generalized Lymphadenopathy

Take a careful history, paying attention to epidemiologic features, including travel, animal exposures, tick bite, unpasteurized milk consumption, immunization status, blood transfusion, drug exposures, and review the HIV risk factors for the mother and child.

Consider whether the child appears ill or well to determine the pace of evaluation and differential diagnosis.

Identify associated signs and symptoms, including fever and weight loss, and perform a thorough review of symptoms.

Identify the location and characteristics of lymph nodes, associated organomegaly, musculoskeletal findings, and rash.

Perform a laboratory evaluation, including CBC, CRP, ESR, serum hepatic enzymes, LDH, ferritin, and blood cultures, and obtain a chest radiograph.

Perform serologic testing based on clinical risk; consider EBV, CMV, HIV, *Mycoplasma*, *Treponema*, *Brucella*, *Bartonella*, *Histoplasma, Francisella,* HHV-6, HHV-8. Perform tuberculin skin testing.

Consider a lymph node biopsy, and plan specific testing of the specimen.

CBC, Complete blood cell count; CMV, cytomegalovirus; CRP, C-reactive protein; EBV, Epstein-Barr virus; ESR, erythrocyte sedimentation rate; HHV, human herpesvirus; HIV, human immunodeficiency virus; LDH, lactate dehydrogenase.

Systemic infections are the most common causes of generalized lymphadenopathy. Many conditions characterized by generalized adenopathy also cause hepatic or splenic enlargement or initially cause regional adenopathy. Differentiating features of characteristic syndromes are listed in Table 16.4.

[a] Other includes particularly axillary, inguinal, epitrochlear, mesenteric, occipital, and supraclavicular adenopathy, depending on disease (see text for details for specific diseases).

A, Atypical; CMV, cytomegalovirus, H, predominantly hepatomegaly; HHV, human herpesvirus; HIV, human immunodeficiency virus; IAHS, infection-associated hemophagocytic syndrome; S, predominantly splenomegaly; ++++, characteristic association; +++, frequent association; ++, occasional association; +, rare association; —, not applicable or unknown.

Congenital Syndromes.

One-third of infants who have congenital toxoplasmosis show signs and symptoms of acute infection. Many infants have splenomegaly (90%), hepatomegaly (70%), or generalized adenopathy (68%). Hepatosplenomegaly is diagnosed in 50% to 75% and generalized lymphadenopathy in 20% to 50% of infants with congenital rubella. These manifestations usually resolve over a few weeks. Generalized lymphadenopathy is uncommon in congenital herpes simplex and CMV infections. Infants with intrauterine HIV infection have generalized, painless lymphadenopathy. Lymph node biopsy results can demonstrate a variety of patterns, including follicular hyperplasia, angioimmunoblastic changes, and atrophy.

Hepatosplenomegaly occurs in almost all infants with early congenital syphilis. Generalized lymphadenopathy is described in 50% of patients. Nodes can be 1 cm or larger and usually are nontender. Enlarged epitrochlear nodes are relatively unique to congenital syphilis.

Spirochetal Infections.

Rash and generalized, painless lymphadenopathy occur in 90% of patients with secondary syphilis. Enlargement of the epitrochlear nodes is a unique and common finding. In 70% of patients, rash and lymphadenopathy are accompanied by constitutional symptoms of fever, malaise, anorexia, and weight loss.

In leptospirosis, generalized lymphadenopathy, hepatosplenomegaly, and constitutional symptoms of muscle tenderness, conjunctival injection, and rashes are seen in the first septicemic stage. The first clinical manifestation of Lyme disease is the typical annular rash, erythema migrans. Untreated, almost 25% of patients have dissemination that leads to secondary lesions of erythema migrans. Patients also complain of fever, headache, myalgia, malaise, and arthralgia, and they can have nontender regional or generalized lymphadenopathy.

Rickettsia, *Ehrlichia*, and *Anaplasma* Infections.

After an incubation period of 1 to 2 weeks, the initial mite bite lesion and necrotic eschar can be seen in patients with scrub typhus. This coincides with the onset of the main characteristic features of the disease, which are fever, headache, rash, and generalized lymphadenopathy. Lymphadenopathy is particularly prominent in the axilla, neck, and inguinal areas. Hepatosplenomegaly and conjunctival injection are common.

Sennetsu fever caused by *Neorickettsia sennetsu* has been found in Japan and Southeast Asia. The infection is likely acquired from eating raw fish.[8] Abrupt onset of fever, chills, headache, malaise, sore throat, and muscle and joint pains is accompanied by hepatosplenomegaly and generalized, tender lymphadenopathy. Posterior auricular and posterior cervical adenopathy are particularly prominent. Generalized lymphadenopathy is not found in other rickettsial infections (e.g., *Rickettsia rickettsii* infection) and occurs inconsistently in *Ehrlichia* and *Anaplasma* infections.

Bartonella Infections.

In the mountain valleys of Peru, Ecuador, and southwest Colombia, between the altitudes of 500 and 3400 m, *Bartonella bacilliformis* infection can be transmitted by the sandfly vector or by blood transfusion, causing Oroya fever. In the acute stage, cells of the reticuloendothelial system contain many organisms after phagocytosis and destruction of infected, deformed red cells. Fever, headache, and muscle and joint pain are accompanied by anemia and generalized, painless lymphadenopathy. Splenomegaly occurs only in patients with intercurrent infection.

B. henselae infection most commonly is associated with prominent regional lymphadenopathy related to the site of inoculation during a cat's scratch. Cat-scratch disease occasionally manifests with generalized lymphadenopathy, splenomegaly, and granulomatous hepatitis, especially in the immunocompromised host. In most instances of generalized lymphadenopathy, only two or three sites are involved, suggesting that separate inoculations might have occurred in some cases.

Enteric Infections.

Enteric fever caused by *Salmonella* spp. primarily affects the lymphoid tissue in Peyer patches in the ileum, the lymphoid follicles of the cecum, and the mesenteric nodes. About 50% of patients have hepatosplenomegaly. Occasionally, patients have generalized lymphadenopathy, particularly involving cervical nodes. Lymphoid tissue undergoes consecutive stages of hyperplasia, necrosis, ulceration, and healing. Suppurative lymphadenitis has been described.

Yersinia pseudotuberculosis and *Y. enterocolitica* infections have been associated with terminal ileitis and mesenteric adenitis, in which mesenteric lymph nodes are enlarged and can become necrotic and intensely suppurative. Concurrently enlarged inguinal and, rarely, cervical and hilar nodes have been described.

Pulmonary Infections.

Although rare, legionellosis in children can manifest with nonspecific symptoms and occasionally with findings of rash, splenomegaly, and lymphadenopathy. Pneumonia caused by *Mycoplasma pneumoniae* infection is accompanied by lymphadenopathy, particularly cervical, in about 25% of cases; mediastinal and hilar lymphadenopathy also can occur.

Tuberculosis usually is characterized by mediastinal and occasionally by cervical lymphadenopathy. Protracted hematogenous disease can cause high fever, hepatosplenomegaly, and generalized lymphadenopathy.

Rarely, symptomatic, disseminated coccidioidomycosis occurs within weeks or months after the initial localized pulmonary infection; most frequently, extrapulmonary spread is to bone, soft tissue, lymph nodes, and meninges. Tissue reaction primarily is granulomatous but can be accompanied by acute inflammation.

In acute disseminated histoplasmosis in infants, the reticuloendothelial system has a high density of yeast forms compared with mycelial forms. Hepatosplenomegaly and intra-abdominal lymphadenopathy are common, and one-third of patients have peripheral lymphadenopathy. In acute pulmonary histoplasmosis, lymphohematogenous spread involves lymph nodes in the neck (where suppuration of supraclavicular or cervical nodes can occur), mediastinum, liver, and spleen.

Paracoccidioidomycosis is endemic in most countries of Latin America, particularly Brazil. The disease almost always is disseminated, with a predilection for the reticuloendothelial system. Peripheral lymphadenopathy occurs in 75% of children with the acute or subacute forms. Cervical, inguinal, mesenteric, or mediastinal lymphadenopathy is almost universal. Lymph nodes vary in size, number, and consistency, Over time, abscesses and fistulas form. Masses of lymph nodes (frequently with caseation) can be seen, and patients usually have hepatosplenomegaly.

Other Bacterial Infections.

Acute onset of symptoms occurs in 50% of patients with brucellosis. As organisms are ingested by mononuclear phagocytes, disease is localized primarily in the lymph nodes, liver, spleen, and bone marrow. Noncaseating granulomas that are indistinguishable from sarcoidosis are the usual finding in liver biopsy specimens.

Lymphadenitis is a common manifestation of tularemia. Although regional involvement (with the site depending on whether acquisition was oropharyngeal or tick related) is the most common presentation, multiple sites can be involved. Hepatosplenomegaly was diagnosed in 35% of infected children in one series.[9]

Generalized lymphadenopathy is rarely described as a feature of scarlet fever. It may be more typical of the severe toxic form of the disease.

Exanthematous Syndromes.

Studies of rubella virus inoculation in adolescents and young adult volunteers demonstrated that suboccipital and posterior auricular lymphadenopathy is most characteristic, but generalized involvement can occur.[10] Pharyngitis and cervical lymphadenopathy are common in measles during the exanthematous period. Generalized lymphadenopathy with suboccipital, posterior auricular, and mediastinal involvement and splenomegaly are also common.

Generalized lymphadenopathy is an uncommon manifestation of varicella-zoster viral infection. It is more often related to secondary bacterial infections.

Clinically, parvovirus B19 infection most often causes erythema infectiosum. However, a mononucleosis-like syndrome with generalized lymphadenopathy and hepatosplenomegaly also has been described.

Mononucleosis Syndromes.

Lymphadenopathy in Epstein–Barr virus (EBV)–associated mononucleosis most prominently involves anterior and posterior cervical nodes, but diffuse lymphadenopathy often involves the occipital, supraclavicular, axillary, epitrochlear, inguinal, and mediastinal lymphatic chains. Enlarged nodes usually are nontender or minimally tender and have no overlying erythema, and they are most prominent during the second to fourth week of illness. Splenomegaly occurs in 50% and hepatomegaly in 30% to 50% of cases.

In children, cytomegalovirus (CMV) is a less common cause of mononucleosis than EBV, but lymphoid manifestations are similar.

In one study of 124 children with the mononucleosis syndromes, fever, hepatosplenomegaly, rashes, and upper airway obstruction were found with equal frequency in infections caused by EBV or CMV. Cervical lymphadenopathy was more common with EBV (93% of cases) than CMV (75%).

Clinical disease caused by human immunodeficiency virus (HIV) in infants and young children is characterized by generalized lymphadenopathy, hepatosplenomegaly, failure to thrive, intermittent fever, chronic or recurrent diarrhea, parotitis, chronic dermatitis, and recurrent infections. In older children and adults, a mononucleosis-like syndrome (i.e., seroconversion syndrome) can occur weeks after HIV infection and includes generalized lymphadenopathy, fever, malaise, myalgia, headache, sore throat, diarrhea, and rash. Lymphadenopathy can involve several sites and can persist for months. Lymph nodes are discrete, nontender, and nonsuppurative; biopsy reveals follicular hyperplasia. With progression to acquired immunodeficiency syndrome (AIDS), lymphocyte depletion occurs. A biopsy specimen from rapidly enlarging nodes should be examined to exclude malignancy. Multicentric Castleman disease can occur in HIV-infected patients (discussed later).

Patients with anicteric hepatitis A or B can manifest a mononucleosis-like syndrome, commonly characterized by posterior cervical lymphadenopathy. Generalized lymphadenopathy is unusual; splenomegaly occurs in 15% of cases.

The most common findings in symptomatic acquired toxoplasmosis are fatigue and lymphadenopathy without fever. Nodes are discrete, may or may not be tender, and do not suppurate. The cervical, suboccipital, supraclavicular, axillary, and inguinal nodes are most often involved. Lymphadenopathy can be localized or generalized, including involvement of the retroperitoneal and mesenteric nodes. Lymphadenopathy can simulate lymphoma.

Miscellaneous Viral Infections.

The usual onset of adenoviral pharyngoconjunctival fever is abrupt, with sore throat, headache, generalized aches and pains, eye irritation or pain, and fever. Some degree of anterior and posterior cervical lymphadenopathy occurs in most patients. Preauricular lymphadenopathy is surprisingly uncommon, and generalized lymphadenopathy is found in 10% to 20% of patients. Hepatosplenomegaly is common. Generalized lymphadenopathy occasionally occurs in nonspecific illnesses caused by enteroviruses.

Tropical Syndromes.

During the acute phase of symptomatic Chagas disease (caused by *Trypanosoma cruzi*), patients have generalized lymphadenopathy, moderate hepatosplenomegaly, rash, vomiting, diarrhea, and neurologic and cardiac changes. At various stages of African trypanosomiasis, the hemoflagellate trypanosomal protozoans *(Trypanosoma brucei rhodesiense* and *T.b. gambiense)* can be found in lymphatics and lymph nodes. Patients can have fever, posterior cervical lymphadenopathy, and local chancre.

In visceral leishmaniasis (i.e., kala-azar), the principal histopathology is the result of macrophage infection and reticuloendothelial hyperplasia. Patients have massive splenomegaly and generalized lymphadenopathy with pancytopenia.

In filarial infections, lymphangitis with involvement of regional nodes is more common than generalized lymphadenopathy. Hematogenous dissemination by way of the thoracic duct, however, can lead to generalized adenopathy.

Katayama fever (i.e., acute schistosomiasis) occurs with severe schistosomal infestation. Generalized, nontender lymphadenopathy, splenomegaly, and hepatomegaly with tenderness are common findings in addition to fever, headache, myalgia, weakness, and gastrointestinal symptoms.

Generalized lymphadenopathy is an integral part of several tropical viral hemorrhagic fever syndromes (see Table 16.4).

Other Causes of Generalized Lymphadenopathy

Drug-Induced Hyperplasia Related to Hypersensitivity.

Drug reaction with eosinophilia and systemic symptoms (DRESS) syndrome is recognized as a great clinical mimicker because the major clinical features also occur in other systemic disorders.[11] Localized or generalized lymphadenopathy can appear 1 to 2 weeks after beginning phenytoin or other anticonvulsant medications such as carbamazepine. A severe, pruritic, maculopapular rash with fever, hepatosplenomegaly, jaundice, anemia, leukopenia, and plasmacytosis in blood and bone marrow occurs concurrently with or after lymphadenopathy. Other agents that have been associated with generalized lymphadenopathy or DRESS syndrome, or both, include pyrimethamine, antileprosy and antithyroid drugs, isoniazid, aspirin, barbiturates, penicillin, minocycline, iodides, sulfonamides, abacavir, nevirapine, allopurinol, and phenylbutazone.

Inherited Immunodeficiency Syndromes.

Generalized lymphadenopathy often is characteristic of inherited immunodeficiency syndromes (e.g., Wiskott-Aldrich syndrome, common variable immunodeficiency) (see Box 16.4). Detection of dysregulated lymphoproliferation in these patients with underlying chronic generalized lymphadenopathy can be difficult. More than 5% of patients with Chédiak-Higashi syndrome have an accelerated phase of disease with generalized lymphadenopathy and hepatosplenomegaly.

Lymphadenopathy with or without dermatitis is a common early feature of chronic granulomatous disease and occurs in almost all patients. Although cervical lymphadenopathy is most common, femoral, inguinal, hilar, mediastinal, and generalized adenopathy also are observed. Typically, early signs of inflammation such as fever, pain, and local inflammation are lacking, and affected nodes suppurate chronically (i.e., cold abscesses). The nodes have caseating or noncaseating granulomas with central necrosis, a reaction to inadequate killing of intracellular and extracellular organisms.

Hodgkin and Non-Hodgkin Lymphoma.

Lymphadenopathy can result from malignant transformation of cells intrinsic to the node or from metastatic spread of cells extrinsic to the node (Box 16.3). Primary neoplasms of lymph nodes include the lymphomas and histiocytosis.[12] Data from the American Cancer Society for 2014 show that lymphomas account for approximately

10% of cancers in children younger than 15 years of age, and leukemia and central nervous system tumors account for 30% and 21%, respectively.

Box 16.3

Noninfectious Causes of Generalized Lymphadenopathy

Inherited immunodeficiency syndromes

- Chronic granulomatous disease
- Wiskott-Aldrich syndrome
- Chédiak-Higashi syndrome

Papular acrodermatitis (i.e., Gianotti-Crosti syndrome)

Sarcoidosis

Hyperthyroidism

Drug-induced hyperplasia or hypersensitivity

Autoinflammatory and autoimmune disorders

Lipid storage diseases

Other lymphoid hyperplasia syndromes

- Hemophagocytic lymphohistiocytosis
- Rosai-Dorfman disease
- Kikuchi-Fujimoto disease
- Multicentric Castleman disease

Cancers

- Primary lymphomas and metastatic neoplasms
- Non-Hodgkin lymphoproliferative disorders
- Childhood histiocytoses

Hodgkin lymphoma (HL) in children younger than 16 years accounts for 10% to 15% of the approximately 7880 HL cases diagnosed annually in the United States. Non-Hodgkin lymphoma (NHL) in children makes up about 5% of the 53,370 cases of NHL diagnosed each year. Among childhood NHL cases, lymphoblastic lymphomas (20%), Burkitt lymphoma (19%), anaplastic large cell lymphoma (10%), and diffuse large B-cell lymphoma (22%) are most common. The cure rate for pediatric lymphoma is as high as 90% for certain categories. Lymphoma is among the most curable of all cancers, which emphasizes the importance of early diagnosis.

The most common first clinical manifestation of HL and NHL is painless lymph node enlargement, most often in the cervical (60% to 90% of cases) or supraclavicular chains. Onset of HL typically is subacute and prolonged, but NHL onset can occur rapidly over a few days or weeks. HL is primarily a disease of adolescents and young adults. Of childhood cases, 60% occur in children 10 to 16 years of age, and less than 3% of cases occur in children younger than 5 years.

Constitutional symptoms of fever, weight loss, drenching night sweats, generalized pruritus, and pain affect only 30% of children at the time of presentation. For patients with HL, 90% come to medical attention with an unusual mass or swelling and enlarged, painless supraclavicular or cervical nodes. Up to 70% of patients have mediastinal lymphadenopathy at presentation, making a chest radiograph valuable if the diagnosis is suspected. Involvement of the Waldeyer ring should be considered if high cervical nodes are enlarged.

Hepatosplenomegaly occurs in patients with advanced disease. Left-sided or bilateral cervical or supraclavicular involvement is more common in extramediastinal para-aortic and splenic spread. Mediastinal disease more often accompanies right-sided cervical or supraclavicular disease.

Other Lymphoproliferative Disorders.

Children with congenital or acquired immunodeficiency syndromes (including HIV infection and immunosuppression after organ transplantation) have a risk of developing lymphoproliferative disorders that is 100 to 10,000 times that of age-matched controls. The lymphoproliferative disorders are a heterogeneous group of B-lymphocyte proliferations that range from polyclonal hyperplasia to true monoclonal malignant lymphoma. The child's underlying condition (i.e., inherited, iatrogenic, or acquired) permits expansion of lymphoid cell populations that are more strictly regulated in the healthy child. Defects in immune regulation and surveillance result in unchecked proliferation of subpopulations of cells with new, irreversible cytogenetic aberrations, sometimes eventuating in NHL (Box 16.4). Lymphoproliferative disorders can manifest with a syndrome of fever, pharyngitis, and generalized lymphadenopathy, which in the early stages strongly resembles acute mononucleosis. EBV infection plays an etiologic role.

Box 16.4

Lymphoproliferative Disorders Associated With Immunodeficiency

Inherited immunodeficiency syndromes

- Ataxia-telangiectasia syndrome
- Wiskott-Aldrich syndrome
- Combined immunodeficiency syndromes
- X-linked lymphoproliferative syndrome

Immunodeficiency resulting from solid organ and stem cell transplantation

Viral infections causing immunodeficiency syndromes

- Epstein-Barr virus infection

- Retrovirus infection

Metastatic Neoplasms.

Metastatic involvement of lymph nodes occurs in a variety of nonlymphomatous cancers, including neuroblastoma, the leukemias, and malignancies of the head and neck (i.e., rhabdomyosarcoma, lymphosarcoma, and sarcoma of the parotid gland, thyroid, and nasopharynx).

Histiocytosis.

Childhood histiocytoses are a rare and diverse group of disorders that can cause generalized lymphadenopathy. Diagnosis and treatment are difficult. The histiocytoses are characterized by infiltration and accumulation of macrophages formed from histiocytic stem cells. Cells of the histiocytic system consist of antigen-processing (phagocytic) and antigen-presenting (dendritic) cells. Both are found in normal and reactive lymph nodes. Langerhans dendritic cells primarily are located in the skin but can be found in lymph nodes. Sinus histiocytes are the principal cells involved in phagocytosis of foreign particulate matter, and they are primarily located in lymph node sinuses.

The pathophysiology of histiocytoses is thought to be uncontrolled immunologic stimulation of normal antigen-processing cells rather than malignant transformation. Lymphadenopathy is a frequent manifestation.

Hemophagocytic Lymphohistiocytosis.

Hemophagocytic lymphohistiocytosis (HLH) is characterized by reactive histiocytic hyperplasia with leukoerythrophagocytosis in a variety of organs. HLH can be inherited or occur sporadically. Genetic and sporadic forms can be triggered by infection and in the setting of other immune dysregulation, including autoimmune disorders and malignancies.

Children with HLH frequently become critically ill, with fever, pancytopenia, generalized lymphadenopathy, and hepatosplenomegaly.[13,14] Laboratory abnormalities include cytopenia; disseminated intravascular coagulation; elevated levels of tissue enzymes, ferritin, and triglycerides; and extremely high levels of cytokines.[15] Bone marrow examination reveals excessive proliferation of benign-appearing histiocytes that are phagocytosing white blood cells, red blood cells, and platelets.

HLH can be triggered by bacteria, fungi, parasites, and most prominently viruses, especially EBV, although the pathophysiology is incompletely understood. Outcomes vary, and they can be poor depending on the type of HLH and underlying conditions. When related to infection other than EBV, recovery rates can be as high as 60% to 70% with treatment of the infection and supportive care[16] (see Chapter 12).

Sinus Histiocytosis With Massive Lymphadenopathy.

Sinus histiocytosis with massive lymphadenopathy (i.e., Rosai-Dorfman disease) is characterized by generalized proliferation of sinusoidal histiocytes.[17] It is a rare disease that occurs in the first 2 decades of life, and the cause of Rosai-Dorfman disease is unknown but thought to be the result of a dysregulated immune system or a response to a presumed infectious agent, or both.

All patients have a history of bilateral cervical lymphadenopathy, often of several months' duration. Lymphadenopathy can be asymmetric, and in 80% of patients, it involves other nodal groups, including the axillary, inguinal, hilar, and mediastinal nodes. In 30% of patients, extranodal disease occurs and involves the nasal and oral cavities, salivary glands, pharynx, tonsils, paranasal sinuses, trachea, orbit, bone, or skin. Systemic manifestations usually include fever, anemia, leukocytosis, an elevated sedimentation rate, and hypergammaglobulinemia. The course usually is indolent with spontaneous regression, but immune-modulating therapy may be required for extensive or progressive disease.

Histiocytic Necrotizing Lymphadenitis.

Histiocytic necrotizing lymphadenitis (Kikuchi-Fujimoto disease) is a benign cause of lymphadenopathy, which is accompanied in 20% of patients by systemic symptoms such as fever, nausea, weight loss, night sweats, arthralgia or hepatosplenomegaly, and leukopenia.[18] The most common manifestation is regional or generalized lymphadenopathy, with or without fever.

The median age of onset is 30 years, but the disease has occurred in children 2 to 18 years of age. Lymph node histologic examination reveals reactive histiocytes and large immunoblastic lymphoid cells. Focal necrotic lesions occur in the paracortical areas of lymph nodes.

The cause is thought to be dysregulation of a disordered immune system. The prognosis is excellent. Spontaneous resolution of lymphadenopathy occurs within 4 months.

Multicentric Castleman Disease.

Castleman disease is an atypical lymphoproliferative disorder characterized histologically by hyperplasia of lymph nodes with plasma cell predominance and marked capillary proliferation. Castleman disease can be a localized, indolent disease that can be cured by local excision or, particularly in HIV-infected individuals, can be a rapidly progressive disease with a poor prognosis. The multicentric form has been associated strongly with HIV and human herpesvirus 8 (HHV-8).[19,20]

Symptoms include fever, myalgia, and weight loss. Patients have diffuse lymphadenopathy, splenomegaly, and rhabdomyolysis. A pilot study suggested some efficacy for zidovudine and valganciclovir against Castleman disease in HIV-infected adults receiving antiretroviral therapy.[21]

Autoinflammatory and Autoimmune Disorders.

Forty percent of children with juvenile idiopathic arthritis of systemic onset have generalized lymphadenopathy, often preceding joint involvement. Patients have splenomegaly and, less often, hepatomegaly. Seventy percent of children with systemic lupus erythematosus have lymphadenopathy, which is generalized in one-third of them. Hepatosplenomegaly is common. Serum sickness (i.e., hypersensitivity reaction to foreign proteins, often drugs) is characterized by fever, urticaria, edema, polyarthralgia, and generalized lymphadenopathy.

In Sjögren syndrome, a rare disease in children, lymphadenopathy and splenomegaly can be accompanied by parotid and lacrimal gland involvement. Lymphadenopathy in Kawasaki disease usually is not generalized.

Papular Acrodermatitis.

Papular acrodermatitis of childhood (i.e., Gianotti-Crosti syndrome) is a distinctive eruption observed in children 6 months to 12 years of age. It is associated with malaise, low-grade fever, generalized lymphadenopathy, and hepatomegaly (when accompanied by hepatitis B viremia). The discrete, 1- to 5-mm, flat-topped, firm papules that appear in groups on the face, buttocks, limbs, palms, and soles resolve spontaneously within 3 weeks, whereas lymphadenopathy and hepatomegaly can persist for months. The eruption has been associated with several viral syndromes, notably hepatitis B and C infection.

Sarcoidosis.

Sarcoidosis is a multisystem granulomatous disease of unknown cause. It affects young adults, and most commonly manifests as asymptomatic, bilateral hilar and paratracheal adenopathy, often with parenchymal lung involvement. Generalized lymphadenopathy with prominent cervical involvement is the most common finding in children. Enlarged nodes are discrete, painless, and freely movable.

Characteristic histologic findings are epithelioid cell tubercles with little or no necrosis. Other findings result from local granuloma formation and include changes in the eyes, skin, liver, spleen, and parotid glands. Biopsy results of a supraclavicular node are diagnostic in 85% of cases.

Lipid Storage Diseases.

In Niemann-Pick, Gaucher, Wolman, and Farber diseases, lipid-laden histiocytes accumulate in the lymph nodes, liver, or spleen, resulting in detectable enlargement. Diagnosis typically is established by some combination of biopsy, genetic testing, and enzyme assays.

Miscellaneous Disorders.

Hyperthyroidism is associated with generalized lymphoid hyperplasia. Beryllium exposure can result in granulomatous lymphadenopathy, which can be generalized.

Cervical Lymphadenitis and Neck Infections

Emily A. Thorell

Epidemiology

Neck masses in children, unlike those in adults, seldom represent ominous disease. Most (95%) masses are enlarged or inflamed lymph nodes and are acute in nature. In one series, 44% of children younger than 5 years had palpable lymph nodes.[1] Other masses are congenital cysts and sinuses (3%), vascular malformations, salivary and thyroid anomalies, benign and malignant neoplasms, traumatic injuries, and nonlymphatic infections. Malignancy accounts for 10% to 15% of children hospitalized for evaluation of a persistent neck mass.[2-4] Although malignancy is uncommon, prompt diagnosis is crucial. Recent US trends show that the incidence of head and neck malignancies among children younger than 15 years increased at a greater rate than childhood cancer in general.[5]

Cervical lymphadenopathy (enlargement) and lymphadenitis (inflammation) are very common; only a few primary studies of etiology are recent and represent a minority of cases. Attempts to delineate the causes and causative agents of acute lymphadenitis have been based on analysis of specimens obtained through needle aspiration and surgical biopsy, or by serologic testing.

Staphylococcus aureus or *Streptococcus pyogenes* is isolated from 40% to 80% of culture-positive cases after aspiration of acutely inflamed, unilaterally inflamed nodes.[6,7] Community-acquired methicillin-resistant *S. aureus* (CA-MRSA) has emerged in more recent years.[8,9] Anaerobic organisms outnumber aerobic and facultative organisms in normal oropharyngeal flora by more than 10:1. In a study from 1980, anaerobic bacteria were isolated in 38% of cases when careful attention was paid to specimen collection and culture.[10] A 2013 study showed that anaerobic organisms were isolated in only 2% of anaerobic cultures in 277 patients requiring surgical intervention; however, 32% of cultures had no isolate.[11] Depending on many factors, especially pretreatment with antimicrobial therapy, no pathogen is isolated in at least 25% of cases of acutely inflamed nodes.[7,10]

For persistent cervical masses, biopsy may be needed for diagnosis. One large study from 1963 examined the biopsy results of persistent cervical masses in 267 children.[3] Congenital cyst or cystic hygroma was found in 60%, malignant tumors in 16%, benign tumors in 7%, nonspecific lymphoid hyperplasia in 10%, and tuberculous granuloma in 7%. The 46 malignant tumors were as follows: 20 lymphosarcoma or Hodgkin disease, 11 neurogenic tumors (neuroblastoma, neurofibroma, neurofibrosarcoma), 11 thyroid tumors, and 4 parotid tumors.

In a review of peripheral lymph node excisional biopsies performed in 239 children, a specific cause was found in only 41% of cases.[12] Of all excised nodes, 76% were located in the neck. Reactive hyperplasia accounted for 52% of cases, granulomatous diseases for 32%, neoplasia for 13% (cases suggestive of lymphoma before biopsy were excluded), and chronic lymphadenitis for 3%. Of the 31 cases of malignancy, Hodgkin lymphoma and non-Hodgkin lymphoma (NHL) accounted for 24, neuroblastoma for 4, and rhabdomyosarcoma for 3 cases. In this series, generalized lymphadenopathy was associated most often with reactive hyperplasia. Close follow-up of patients with a diagnosis of nonspecific reactive hyperplasia is important because studies indicate that up to 25% of such patients ultimately develop life-threatening lymphoreticular disease.[2,8,13,14]

The use of polymerase chain reaction (PCR) testing of surgical specimens has improved diagnostics in persistent, culture- or serology-negative cases. In a 2009 study of 60 children treated surgically for suspected infectious persistent cervical lymphadenitis, an etiology was identified in 82%.[15] Methods combining conventional stain and culture with PCR to amplify the eubacterial 16S ribosomal RNA followed by more specific pathogen amplification were used. Organisms identified were both tuberculous and nontuberculous *Mycobacterium* spp. (62%), followed by *Bartonella* spp. (10%) and *Legionella* spp. (10%). Interestingly, this is the first case series describing *Legionella* as a cause of persistent cervical lymphadenitis; diagnosis was made by PCR testing. As molecular diagnostics become more available, spectrum of causative agents of adenitis likely will increase.

Surgical biopsy results from children in developing countries show a slightly different spectrum of disease. A review of 1332 patients younger than 15 years over a 23-year span in South Africa showed 48% reactive nodes, 25% *Mycobacterium tuberculosis,* 11.6% neoplasm, and 11.5% chronic granuloma. Miscellaneous etiologies included syphilis, yaws, toxoplasmosis, sinus histiocytosis, and Kaposi sarcoma.[16]

Age is useful in predicting etiology of infection (Table 17.1). Group B *Streptococcus* is a common cause of lymphadenitis in young infants; *S. aureus* in infants and children; and *S. pyogenes, S. aureus,* and nontuberculous *Mycobacterium* (NTM) spp. in children 1 to 4 years old. Acute cervical lymphadenitis may be more common in the young child because of an inability to localize the organism to the initial nasal or pharyngeal site of attachment. In children aged 5 to 15 years and adults, anaerobic infection, toxoplasmosis, cat-scratch disease, and tuberculosis are important considerations.

TABLE 17.1

Age-Specific Causes of Cervical Lymphadenitis

	Patient Age			
Organism	**Neonate**	**2 Months–1 Year**	**1–4 Years**	**5–18 Years**
Group A *Streptococcus*	–	–	+	++
Group B *Streptococcus*	++	+	–	–
Staphylococcus aureus	+	++	++	++
Nontuberculous *Mycobacterium*	–	–	++	+
Bartonella henselae	–	+	++	++
Toxoplasma gondii	–	–	+	+
Anaerobic bacteria	–	–	+	++

++, Frequent cause; +, occasional cause; –, rare cause or never a cause.

Lymphatic Flow and Fascial Spaces of the Head and Neck

A complex and efficient lymphatic system has evolved to defend against microbial invasion of the head, neck, nasopharynx, and oropharynx, as shown in Table 17.2 and Fig. 17.1. There are three interrelated lines of defense. The ring of Waldeyer is composed of a circle of adenoidal, tonsillar, and lingual lymphoid tissue (see Chapter 16). A collar of superficial satellite lymph nodes runs along the lower margins of the jaw and encircles this ring. This outlying collar of nodes of the head consists of the occipital, postauricular, preauricular, parotid, and facial groups. Nodes of the neck are the salivary gland–associated submaxillary and submental nodes and the vertically oriented superficial and deep cervical chains.

TABLE 17.2

Physiology of Lymph Flow in the Head and Neck

Lymph Node Group	Areas Drained
HEAD	
Postauricular (mastoid)	Temporal and parietal scalp; posterior wall of ear canal; upper half of pinna
Occipital	Posterior scalp; skin of upper, posterior side of neck
Preauricular	Anterior and temporal regions of scalp; anterior ear canal and pinna; lateral conjunctivae
Parotid	Root of nose; eyelids; temporal scalp; exterior auditory meatus; parotid glands; middle ear; floor nasal activity; posterior palate
Facial	Eyelids, conjunctivae; skin and mucous membranes of nose and cheek; nasopharynx
NECK	
Submental	Central lower lip; floor of mouth; skin of chin; tongue tip
Submandibular (submaxillary)	Buccal mucosa; side of nose; medial palpebral commissure; upper lip; lateral part of lower lip; gums, anterior part of tongue margin, teeth
Superficial cervical	Anterior: superficial anterior neck tissues including skin, lower larynx, thyroid, cranial trachea
	Posterior: lower ear canal; parotid region
Superior deep cervical	Tonsil, adenoid; posterior scalp and neck; tongue, larynx, palate; thyroid; nose, nasopharynx; esophagus; paranasal sinuses; all nodes of head and neck except inferior deep cervical
Inferior deep cervical (scalene, supraclavicular)	Dorsal scalp and neck; superficial pectoral region of arm; superior deep cervical nodes; larynx, trachea; thyroid
	Right: left lower lobe, lingula, right lung and pleura
	Left: left upper lobe; entire abdomen

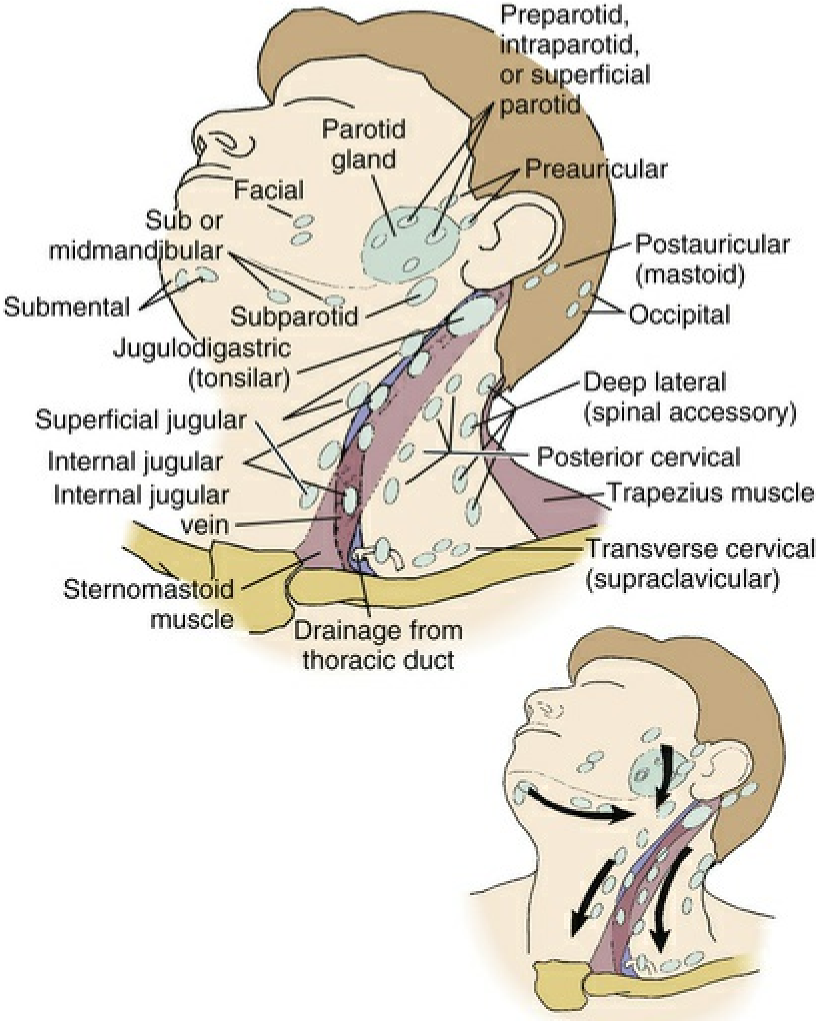

FIGURE 17.1 Lymphatic flow in the head and neck.

Occipital nodes often are enlarged when generalized lymphadenopathy is present; regional enlargement is almost always infectious and is due to tinea capitis, pediculosis capitis, seborrheic dermatitis, or scalp cellulitis or abscess. Enlargement of preauricular nodes reflects local skin or conjunctival infection. Asymptomatically enlarged parotid glands raise the possibility of malignancy.

Specific Lymph Node Groups

Superficial Cervical Nodes

The superficial cervical nodes in the neck are a disparate group composed roughly of three vertical chains. The *deep lateral or spinal* *accessory chain* runs behind the posterior border of the sternocleidomastoid (SCM) muscle and along the spinal accessory nerve. The *superficial cervical chain* follows the external jugular vein, which runs obliquely across the surface of the SCM muscle to empty into the subclavian vein in the supraclavicular triangle. The superficial *anterior chain* runs in the midline from the chin to the suprasternal notch and comprises, in descending order, the infrahyoid, prelaryngeal, pretracheal, and anterior cervical nodes. The term *posterior cervical nodes* is nonspecific, referring to nodes of the spinal accessory chain and those of the superficial cervical chain that lie over and behind the SCM muscle; lymph nodes anterior to the SCM muscle are designated as in the anterior triangle and those behind as in the posterior triangle.

Deep Cervical Nodes

The *deep cervical chain* of lymph nodes runs from the base of the skull to the root of the neck in close approximation to the internal jugular vein on the carotid sheath, and under the SCM muscle. This chain contains numerous large nodes and is divided into superior and inferior deep cervical groups. The *superior group* is above and the *inferior group* is below the point low in the neck where the omohyoid muscle crosses the internal jugular vein. The lymphatic channels and nodes in the head and neck connect, and ultimately all empty into the thoracic duct on the left or the lymphatic duct on the right, each of which in turn immediately empties into the respective subclavian vein.

The tonsillar or jugulodigastric node, which drains the palatine tonsil, belongs to the superior deep cervical group and lies at the angle of the mandible just below the posterior belly of the digastric muscle. Other deep cervical nodes lying under the SCM muscle along the internal jugular vein drain the adenoid, larynx, trachea, thyroid, palate, esophagus, paranasal sinuses, nasopharynx, occipital scalp, back of the neck, pinna, and much of the tongue. The large jugulo-omohyoid node that drains the tongue lies just above the omohyoid muscle where it crosses the internal jugular vein, which separates the superior and inferior deep cervical nodes.

Because most lymphatics of the head and neck drain to the submandibular and deep cervical nodes, these nodes are involved in more than 80% of cases of cervical lymphadenitis in young children.

The inferior deep cervical nodes lie low in the neck, below the omohyoid muscle and under and posterior to the anterior clavicular insertion of the SCM muscle. They lie in close approximation to the brachial plexus and to the entrance sites of the thoracic duct and right lymphatic duct into the left and right subclavian veins. All lymph from the head and neck, arms, superficial thorax, lungs, mediastinum, and abdomen passes through these nodes. The left supraclavicular nodes (Virchow-Troisier nodes) drain the left upper lobe of the lung, left mediastinum, stomach, small intestine, kidney, and pancreas. Enlargement of these nodes in the absence of cervical adenopathy suggests intra-abdominal tumor or inflammation (Troisier sign) or intrathoracic disease. The right supraclavicular nodes drain the left lingula and lower lobes as well as the entire right lung, pleura, and right mediastinum. Enlargement of these nodes most often indicates thoracic lesions, especially Hodgkin lymphoma and NHL. Prompt biopsy is indicated in the absence of easily documented pulmonary or cervical infection.

Deep Neck Infections

The fascial system of the neck is complex, but a general anatomic description is useful to understand the deep neck infections. The neck fascia is divided into two layers: the superficial layer and the deep layer. The deep fascia is further divided into the superficial, middle, and deep layers of the deep fascia (Fig. 17.2). The 11 *deep neck spaces* interconnect and include the lateral pharyngeal (parapharyngeal), retropharyngeal, prevertebral, "danger," masticator, submandibular, carotid, pretracheal, peritonsillar, parotid, and temporal spaces.[17]

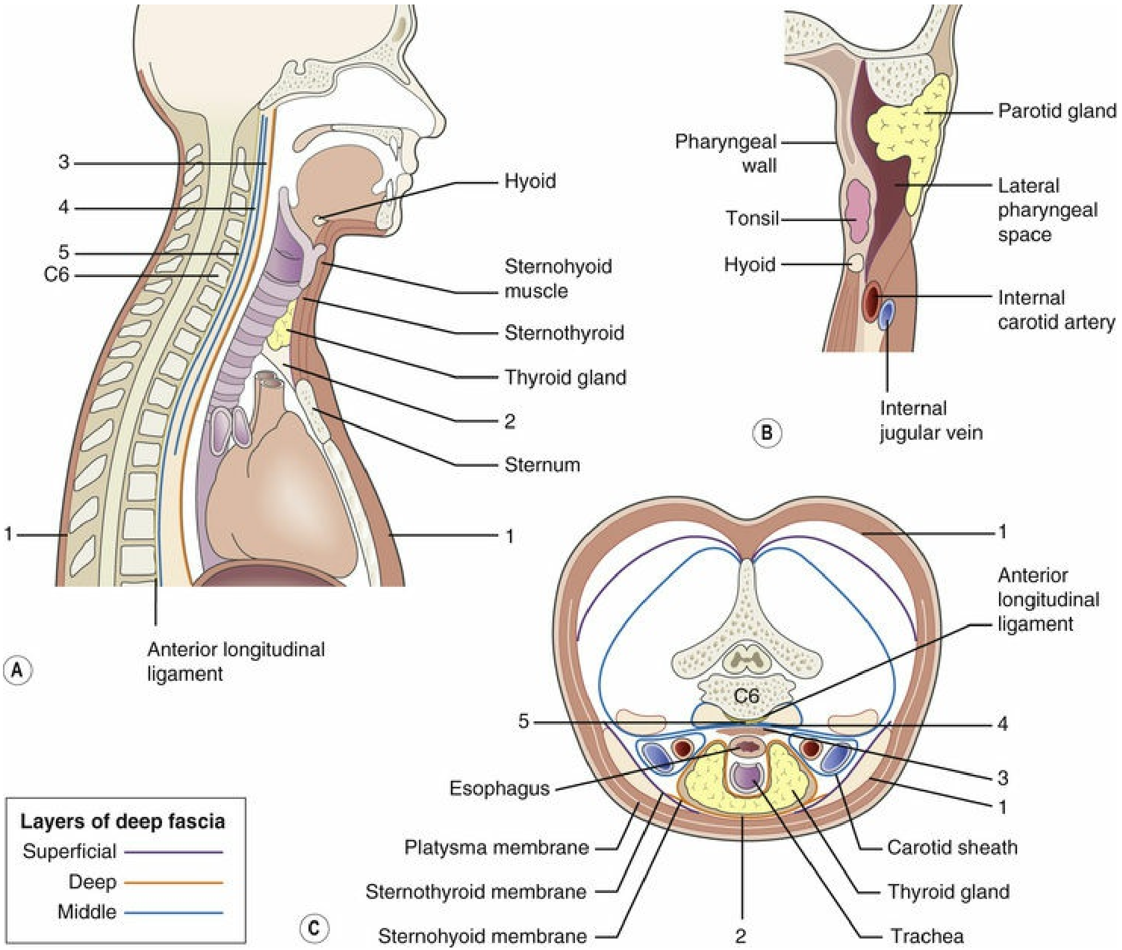

FIGURE 17.2 **Relation of the lateral pharyngeal, retropharyngeal, and prevertebral spaces to the posterior and anterior layers of the deep cervical fascia. (A) Midsagittal image of the head and neck. (B) Coronal image in the suprahyoid region of the neck. (C) Cross section of the neck at the level of the thyroid isthmus. In all illustrations, 1: superficial space; 2: pretracheal space; 3: retropharyngeal space; 4: danger space; 5: prevertebral space.** (From Mandell GL. Mandell, Douglas, and Bennett's Principles and Practice of Infectious Disease. 7th ed. St. Louis, Elsevier, 2009. Reproduced with permission of Elsevier.)

The most clinically relevant deep neck spaces include the *submandibular*, *peritonsillar*, *retropharyngeal*, and *lateral pharyngeal spaces*. Infection in the submandibular space is known as *Ludwig angina*. Ludwig angina is a bilateral, brawny cellulitis that originates in the floor of the mouth. Infection of the retropharyngeal space is most common in children aged 2 to 4 years because the several small lymph nodes and space atrophy by adolescence. Infection in this space in older children and adults usually is secondary to direct trauma rather than to lymphatic spread. Cervical adenitis is not a common manifestation because these nodes drain into the prevertebral space; however, mediastinitis and empyema can occur. The peritonsillar space surrounds the palatine tonsil. Peritonsillar abscess is the most common deep neck infection, accounting for 50% of cases, and is more common in adolescents and young adults. Abscess usually is unilateral but can be bilateral. Cervical and submandibular adenopathy also can occur from drainage of the superior deep cervical nodes.[18,19]

The lateral pharyngeal space is a central connection for all other neck spaces, and thus infections can follow infection at various sites; presentation with unilateral cervical adenitis is common. The lateral pharyngeal space is divided into anterior and posterior compartments. Suppurative jugular thrombophlebitis (Lemierre syndrome) is a well-described complication of *Fusobacterium* infection of the posterior compartment, most commonly spread from primary tonsillitis. Along with sepsis because of proximity to the carotid sheath, swelling around the SCM muscle or "bull neck," neck pain and stiffness, and torticollis are common.[18,19] More detailed descriptions regarding neck space infections are found in Chapters 25 and 28.

Oculoglandular Syndrome of Parinaud

The oculoglandular syndrome of Parinaud consists of unilateral, chronic granulomas or ulcers of the conjunctivae associated with preauricular and submaxillary lymphadenitis.[20] Causes are listed in Box 17.1. *Bartonella henselae* infection is most common. Primary conjunctival inoculation causes grey or yellow granulomatous nodules or areas of focal necrosis, often surrounded by significant conjunctival chemosis and palpebral inflammation. Recovery without sequelae (except for occasional mild conjunctival scarring) occurs within 2 to 3 months. Antimicrobial therapy usually is given but has not been proved to hasten resolution.[21]

Histoplasma capsulatum

Coccidioides immitis

Paracoccidioides spp.

Sporothrix schenckii

Parasites

Trypanosoma spp.

Rickettsia

Rickettsialpox

Rickettsia spp.

Infectious Causes of Lymphadenitis

For purposes of predicting etiology, most cases of infectious cervical lymphadenitis can be divided into the following three categories (with some overlap): (1) acute bilateral lymphadenitis; (2) acute unilateral lymphadenitis; and (3) subacute (chronic) lymphadenitis.

Acute Bilateral Lymphadenopathy/Lymphadenitis

Acute bilateral lymphadenopathy (less commonly lymphadenitis) most often is a localized response to acute pharyngitis or part of a generalized lymphoreticular response to systemic infection in older children. Usually, lymph nodes are small and soft, may or may not be tender, and are not associated with erythema or warmth of the overlying skin. Viral upper respiratory tract infection is the most common cause, followed by pharyngitis due to *S. pyogenes* and *Mycoplasma pneumoniae.*

Epstein-Barr Virus.

Although generalized lymphadenopathy is common in Epstein-Barr virus (EBV) infection, cervical adenopathy is most prominent and is present in 93% of infected children.[22] Enlargement usually is bilateral and most prominent in the posterior cervical chain, followed by the anterior cervical chain. Lymph nodes are enlarged singly or in groups; vary from 5 to 25 mm in diameter; and are firm, discrete, and minimally tender. Moderate splenomegaly occurs in 75% of patients. Significant enlargement of the lymphoid tissue in Waldeyer ring can result in nasopharyngeal and oropharyngeal airway obstruction.

Cytomegalovirus.

Mononucleosis due to cytomegalovirus (CMV) is similar to that due to EBV, although it is more frequent in children younger than 4 years.[22] Cervical adenopathy is less common in CMV infection (75%) than in EBV (95%) infection. Tonsillopharyngitis and sore throat are more common in EBV infection, whereas hepatosplenomegaly, upper airway obstruction, and rashes are more common in CMV infection.

Herpes Simplex Virus Infections.

Cervical, submaxillary, and submental nodes frequently are enlarged and tender during the course of primary gingivostomatitis due to herpes simplex virus (HSV). Primary infections of the conjunctivae and lids are accompanied by preauricular adenopathy. Localized or regional necrotizing lymphadenitis from primary HSV infection also has been reported as a rare occurrence.[23]

Adenoviral Syndromes.

Pharyngoconjunctival fever due to adenovirus is characterized by abrupt onset of fever, pharyngitis, and granular conjunctivitis (unilateral or bilateral). Hyperplasia of the tonsillar, adenoidal, and pharyngeal lymphoid tissue is present. A study from Spain showed that 32% of children with positive pharyngeal cultures for adenovirus had cervical node enlargement.[24] Preauricular adenopathy is surprisingly infrequent. Generalized adenopathy is present in 10% to 20% of patients with pharyngoconjunctival fever, and hepatosplenomegaly is common.

Preauricular adenitis occurs in 90% of patients with epidemic keratoconjunctivitis. One half of patients with the usually unilateral, acute, follicular conjunctivitis also have pharyngitis and rhinitis.[25]

Acute respiratory disease due to adenoviruses generally has significant constitutional as well as localized respiratory symptoms. Bilateral cervical adenopathy is expected.

Enteroviruses.

Nonspecific febrile illness due to coxsackieviruses and echoviruses generally has an abrupt onset. Manifestations include fever, malaise, sore throat, nausea, vomiting, and abdominal pain. Minimal conjunctival and pharyngeal erythema with bilateral cervical adenopathy is present.

Human Herpesvirus 6 and 7 (Roseola).

In one reported series of human herpesvirus 6 (HHV-6) infections in 688 children, mild bilateral cervical adenopathy was present in 31% of cases. Typically, the occipital, posterior auricular, and posterior cervical nodes are involved, but enlargement is modest.[26] HHV-7 also can cause roseola; however, the complete clinical picture of disease has not been defined.[27]

Human Herpesvirus 8.

HHV-8 generally is the etiologic agent of Kaposi sarcoma in severely immunosuppressed patients with human immunodeficiency virus infection. HHV-8 also has been associated with primary effusion lymphoma and multicentric Castleman disease. Primary infection in immunocompetent children, however, can cause fever, sore throat, morbilliform rash, and cervical lymphadenopathy.[28,29]

Rubella Virus.

In patients with experimentally induced rubella, lymph node enlargement begins as early as 7 days before the onset of the rash. Although generalized lymphadenopathy occurs, the nodes most commonly involved are the posterior auricular, suboccipital, and cervical nodes. Tenderness and swelling are most severe on the first day of the rash. Although tenderness of nodes subsides within 1 to 2 days, enlargement persists for weeks.

Parvovirus B19.

A mononucleosis-like syndrome due to parvovirus B19 infection can be associated with bilateral cervical and intraparotid lymphadenopathy. Generalized lymphadenopathy and hepatosplenomegaly also can be present. Facial palsy and parotitis can accompany intraparotid lymphadenopathy.[30]

Mycoplasma pneumoniae.

Physical examination of children and adults with pneumonia due to *M. pneumoniae* reveals cervical adenopathy in 25%, pharyngitis in

50%, and auscultatory findings in 75%. In patients in whom pharyngitis is the major manifestation, 43% have exudative tonsillitis and 50% have cervical adenopathy.

Corynebacterium diphtheriae.

Cervical adenitis is variable in tonsillar and pharyngeal diphtheria. In some cases, adenitis is associated with edema of the soft tissues of the neck ("erasive edema") so severe as to appear as to cause a bull-neck appearance. In other cases, lymphadenitis is minimal.

Acute Unilateral Lymphadenitis.

Table 17.3 summarizes clinical clues to and diagnostic tests for selected causes of unilateral cervical lymphadenitis.

TABLE 17.3

Clinical Clues and Diagnostic Tests for Selected Causes of Unilateral Cervical Lymphadenitis

Organisms	Clinical Clues	Diagnostic Tests
Staphylococcus aureus *Streptococcus pyogenes*	Acute unilateral adenitis; ages 1–4 years; 2- to 6-cm nodes, frequent associated cellulitis; 25%–33% become fluctuant For *S. aureus*, suppuration is rapid; without therapy, 85% of nodes suppurate	Throat culture for *S. pyogenes;* needle aspirate of node for Gram stain and culture
Group B *Streptococcus*	Ages 2–6 weeks; cellulitis-adenitis syndrome; facial or submandibular cellulitis; ipsilateral otitis media	Blood culture and aspirate of node or soft tissue for Gram stain and culture CSF evaluation if cellulitis-adenitis syndrome
Anaerobic bacteria	Older children; dental caries; periapical or periodontal disease present, Lemierre syndrome	Needle aspiration of node for Gram stain and culture; blood culture
Bartonella henselae	Most common cause of chronic unilateral adenopathy; contact with kittens; oculoglandular syndrome; inoculation papule present	Serologic analysis; culture of tissue with granulomas with stellate abscesses on biopsy, PCR
Nontuberculous *Mycobacterium*	Age 1–5 years; no systemic symptoms; no exposure to TB; unilateral submandibular node: normal chest radiograph and ESR; TST usually <15 mm	Characteristic granulomatous reaction; culture of excised node, PCR
Mycobacterium tuberculosis	Age >5 years; systemic symptoms with history of exposure to TB; bilateral lower cervical node involvement; elevated ESR	Positive TST and chest radiograph; culture of gastric aspirate, PCR
Toxoplasma gondii	Fever, fatigue, myalgia, sore throat; discrete <3 cm localized anterior cervical, suboccipital, or supraclavicular nodes; ± mediastinal adenopathy	Serologic analysis (laboratory with special expertise)

CSF, cerebrospinal fluid; ESR, erythrocyte sedimentation rate; PCR, polymerase chain reaction; TB, tuberculosis; TST, tuberculin skin test.

Staphylococcus aureus and *Streptococcus pyogenes*.

S. aureus or *S. pyogenes* infections account for 40% to 80% of cases of acute unilateral cervical lymphadenitis.[6,7] Typically, the patient is a 1- to 4-year-old child with a history of recent upper respiratory tract symptoms (sore throat, earache, coryza) or impetigo and signs of pharyngitis, tonsillitis, or acute otitis media. Few clinical findings distinguish streptococcal from staphylococcal infection.

The infected nodes, usually in the submaxillary or superior deep cervical chain, are 2.5 to 6 cm in diameter and tender, and often the overlying skin is erythematous and warm. Systemic symptoms, bacteremia, or metastatic foci of infection can occur. Occasionally, suppuration and periadenitis are so severe that torticollis is present and individual nodes cannot be palpated. Systemic symptoms such as high fever, toxicity, tachycardia, and flushed facies may be present. In up to one third of cases that come to medical attention, lymph node suppuration and fluctuation develop. Infection caused by *S. aureus* tends to have a longer duration of disease before diagnosis, a higher likelihood of suppuration, and slower resolution (Fig. 17.3).

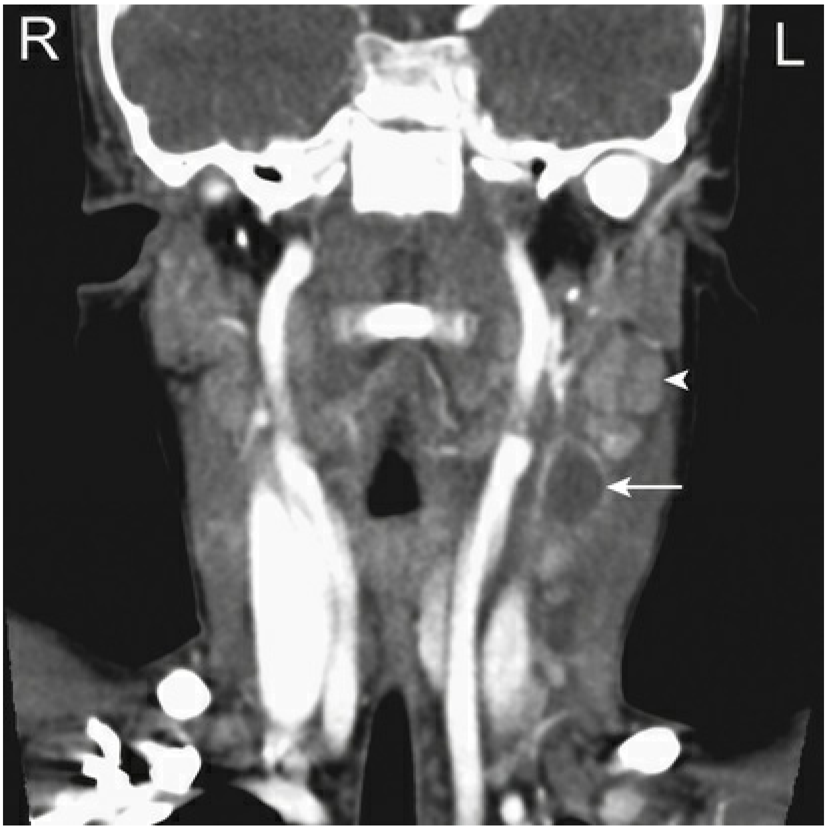

FIGURE 17.3 ***Staphylococcus aureus*** **neck infection. Note multiple left-sided inflamed nodes (*arrow*) and (*arrowhead*) abscess at the level of the hyoid.**

The role of *S. aureus* alone as a cause of acute unilateral lymphadenitis has been questioned. In a study from 1979, node aspirates from 65% of the patients yielded pure growth of *S. aureus*; 41% of these patients exhibited an immune response to one or more of the extracellular antigens of *S. pyogenes*.[31] Additionally, it has been observed that many children improve clinically with penicillin or ampicillin therapy alone, which would not be effective against β-lactamase−producing *S. aureus*. Recent studies suggest a predominant role of *S. aureus* (including CA-MRSA) compared with *S. pyogenes* when etiology is confirmed; however, recent serologic studies have not been performed.[8,9,32]

Streptococcus agalactiae (Group B *Streptococcus*).

Typically, the young infant with group B streptococcal cellulitis-adenitis (submandibular/cervical) syndrome has abrupt onset of fever, poor feeding, and irritability associated with unilateral facial or submandibular swelling that is erythematous and tender.[33] Bacteremia usually is present, and the organism is isolated from the aspirate of cellulitis or a lymph node. Ipsilateral otitis media is common. Meningitis is present in as many as 24% of infants with cellulitis-adenitis.[34] Suppurative submandibular lymphadenitis caused by *S. aureus* sometimes is distinguishable because of manifestation as a discrete mass and the propensity for suppuration.

Anaerobic Bacteria.

In older children with the acute onset of unilateral adenitis, an anaerobic infection secondary to periodontal or dental abscesses should be considered. Such infection can lead to septic thrombophlebitis of the jugular vein, septic pulmonary emboli, and central nervous system infection (Lemierre syndrome; see Chapters 25 and 28). Presentation is with bull neck, severe inflammatory response, systemic toxicity, and several positive blood cultures with isolation of *Fusobacterium* spp. or, less commonly, viridans streptococci.

Francisella tularensis.

Cervical lymphadenopathy alone or concurrent with other regional adenopathy was common in tularemia. In one series, lymphadenopathy (especially cervical nodes) was the most common manifestation, being present in 96% of patients; in 4 of 28 children, cervical nodes were the only enlarged nodes (Fig. 17.4).[35] One third of the children had late suppuration after antibiotic therapy. In untreated cases, the skin over the involved nodes is inflamed, and about 50% of nodes suppurate and drain. In the remainder of cases, the nodes remain firm, enlarged, and tender for several months.

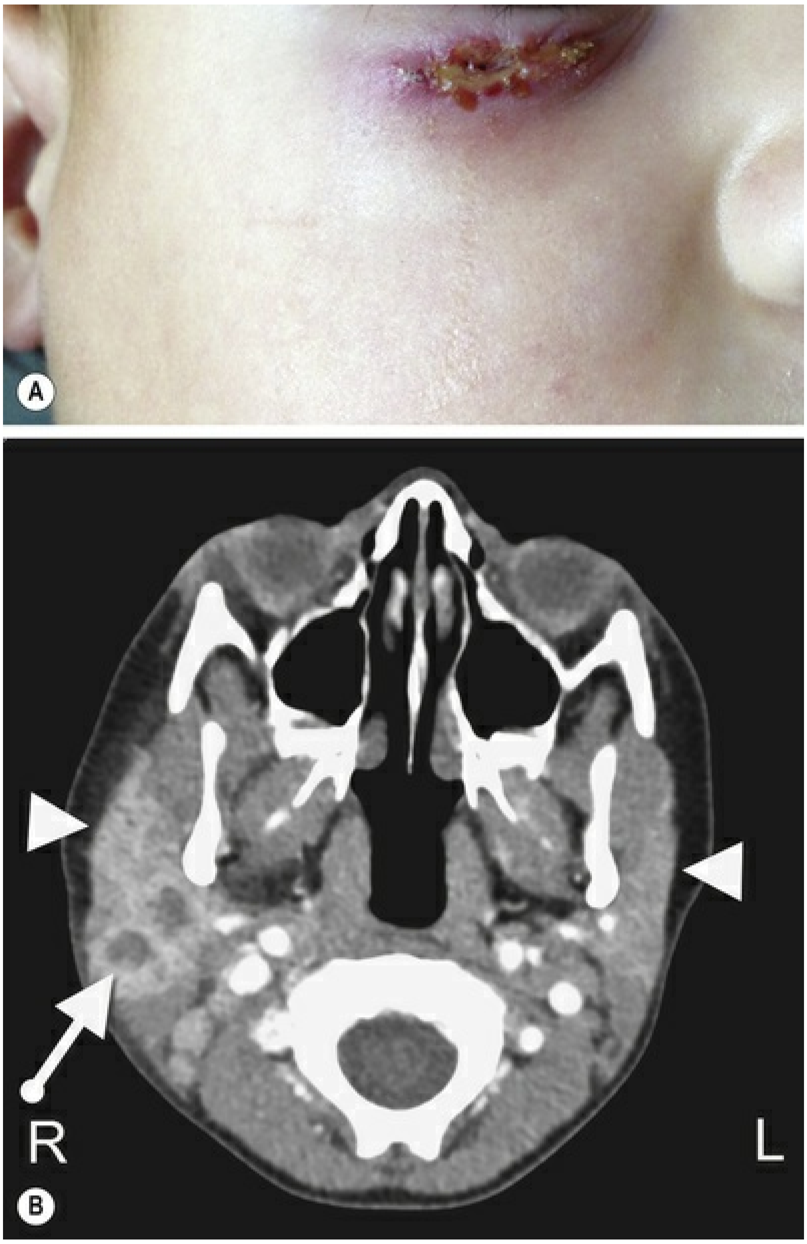

FIGURE 17.4 **Ulceroglandular tularemia in a 6 year old. (A) Ulcer at the site of inoculation with surrounding erythema. (B) Right-sided acute inflammatory parotitis with multiple suppurative lymph nodes within the parotid. Note normal parotid gland on the left.**

In oculoglandular tularemia, the eyelids become edematous, and the conjunctivae are inflamed and painful, with nodules and ulcers. Preauricular, submaxillary, and cervical nodes are enlarged, tender, and painful.

Pasteurella multocida.

After an animal bite or scratch on the head, neck, or upper chest, acute unilateral cellulitis due to *P. multocida* can be associated with tender cervical lymphadenitis.

Yersinia pestis.

Fleas from wild mammals, cats, and dogs in the western United States serve as the vectors for *Y. pestis* (bubonic plague). Organisms are carried in lymphatics to the nearest node, usually causing acutely enlarged, edematous, exquisitely tender, unilateral lymphadenitis with overlying erythema (bubo). Because animal bites occur more commonly on the extremities than around the head and neck, cervical adenopathy is the third most common site of involvement. Fever and other systemic manifestations accompany the appearance of buboes. Untreated, the nodes suppurate and ulcerate.

Unusual Organisms.

Rarely, gram-negative bacilli, *Streptococcus pneumoniae*, group C streptococci, *Nocardia brasiliensis, Yersinia enterocolitica, Staphylococcus epidermidis*, α-hemolytic streptococci, *Legionella* spp., or endemic fungi such as *Histoplasma* or *Coccidioides* spp. are isolated from a node. Immunodeficiencies such as Job syndrome and chronic granulomatous disease should be considered if a catalase-producing gram-positive or gram-negative organism is causative.

Subacute or Chronic Unilateral Lymphadenitis

Mycobacterial infections, cat-scratch disease, and toxoplasmosis are most commonly associated with subacute lymphadenitis. Typical finding is a painless or minimally tender, unilateral, swollen cervical or submaxillary node. If the lymph nodes enlarge and the disease progresses, the overlying skin becomes taut and effaced, with pinkish discoloration (although there is no increase in skin temperature). Skin becomes attached to the underlying mass. If the infection is untreated, fluctuation and spontaneous drainage (with or without formation of sinus tracts) usually follow. Suppuration from toxoplasmosis is rare.

Cat-Scratch Disease.

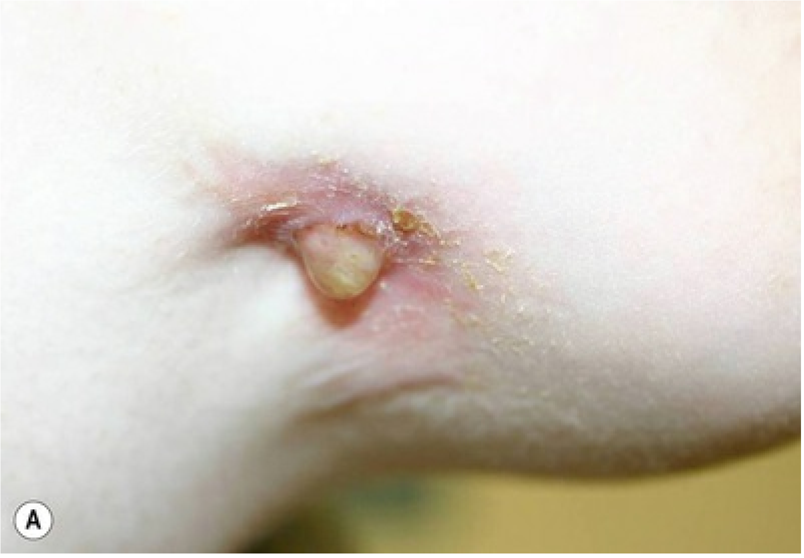
Cat-scratch disease is regional lymphadenitis that follows inoculation of *B. henselae* into damaged skin or mucosal membrane. The most common sites of lymphadenopathy are the axilla (52%) and neck (28%), presumably from scratches on the extremities and cuddling an animal, respectively. Adenopathy can begin 5 days to 2 months after inoculation. Generally, the affected node is solitary, often more than 4 cm in diameter, and tender. Constitutional symptoms usually are mild and include fever in up to 25% of cases. Overlying skin is not red or warm, but suppuration occurs in 30% to 50% of patients brought to medical attention. The oculoglandular syndrome of Parinaud, initially described in cat-scratch disease, is common.[16] Supraclavicular nodes can be involved from scratches on the neck or upper chest. Nonsuppurative nodes diminish in size after 4 to 6 weeks. Treatment probably aborts suppuration of larger nodes (see Chapter 160).

Toxoplasmosis.

In the 10% of patients with acquired toxoplasmosis who are symptomatic, lymphadenopathy and fatigue without fever are the most common manifestations.[36] The nodes most commonly involved are the cervical, suboccipital, supraclavicular, axillary, and inguinal. The involved nodes are discrete, may or may not be tender, and do not suppurate. Adenopathy is localized or involves multiple areas.

Nontuberculous *Mycobacterium.*

Infection due to NTM occurs in children 1 to 4 years old, and cervical adenitis is the most common manifestation in this age group. Organisms are ubiquitous in soil and probably are ingested; infection is localized to a submandibular or single tonsillar node. Bilateral involvement is rare. A recognizably enlarged node is usually the superficial marker of a large, deeper cluster. Initial appearance can be rapid (over 24 hours), with gradual increase in node size over 2 to 3 weeks. Most enlarged nodes are 3 cm or less in diameter, although enlargement to more than 5 cm can occur. Pain, tenderness, and constitutional illness are minimal. Approximately 50% of children with recognized lymphadenitis have fluctuant lesions, and in 10%, spontaneous drainage and sinus tract formation occur (Fig. 17.5A). The skin changes from pink to a distinctive lilac red, with the overlying skin developing a thin, parchment-like quality. In some cases, fluctuation without skin changes develops. Signs and symptoms of *M. tuberculosis* adenitis and NTM adenitis are identical (Fig. 17.5B). Other clinical and epidemiologic features are distinctive. Chest radiograph is normal in children with NTM infection, and an intermediate Mantoux tuberculin skin test results in less than 15 mm induration (usually 5 to 9 mm). Surgical excision generally is recommended unless proximity to nerves is concerning or cosmetic outcome is undesirable. Careful attention must be paid to the facial nerve location because more than 30% of patients have been reported to have some facial nerve injury postoperatively.[37] Incisional drainage is not recommended because the development of sinus tracts is possible. Therapy with antimicrobial agents active against NTM as adjunctive therapy may be useful in some situations[38-40] (see Chapter 135).



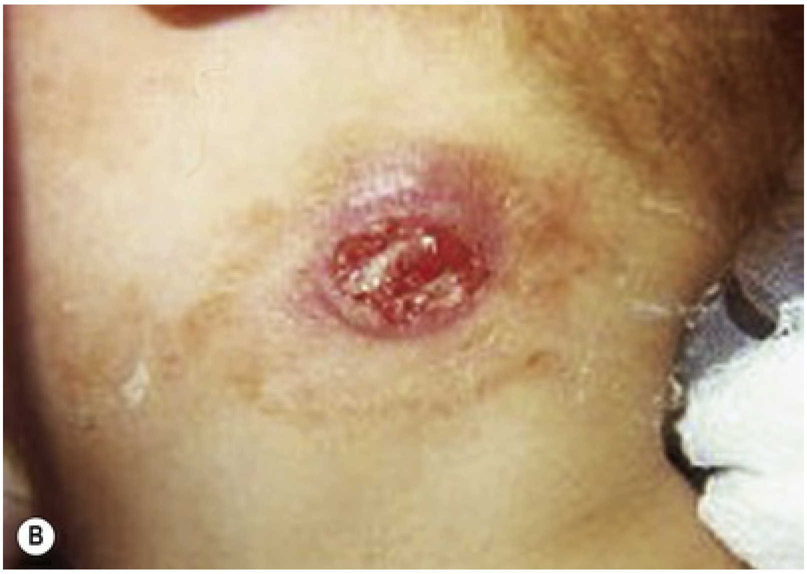


FIGURE 17.5 (A) Draining lymph node due to nontuberculous *Mycobacterium* infection. (B) Draining lymph node due to *Mycobacterium tuberculosis* infection. These are clinically indistinguishable. (A, Courtesy of J. Christenson, Indianapolis, IL.)

Mycobacterium tuberculosis.

Striking enlargement of the superficial regional lymph nodes is an integral part of the primary lower respiratory tuberculous complex. Involvement of the cervical nodes is most often the result of extension from the paratracheal nodes to the tonsillar and submaxillary nodes or from the apical pleurae and upper lung fields by direct spread to the inferior deep cervical (supraclavicular) nodes. Rarely, superficial lymph nodes are enlarged secondary to generalized adenopathy during the course of lymphohematogenous spread of infection (see Fig. 17.5B). Reactivation of quiescent tuberculous infection can manifest initially as localized or generalized adenopathy.

When superficial nodes are involved early in the infection, nodes usually are enlarged, painless, and rubbery.[41] Bilateral enlargement is the rule, but right-sided involvement can predominate. Acute nontuberculous respiratory tract infections can precipitate or aggravate tuberculous lymphadenitis, resulting in local pain and perilymphadenitis. Rarely, the patient is seen with a fluctuant mass and shiny, erythematous overlying skin. These nodes can rupture and drain chronically. Secondary infection with other pyogenic bacteria can occur. In general, clinical features do not distinguish tuberculous and nontuberculous mycobacterial infections, and diagnosis may be difficult if exposure to *M. tuberculosis* is suspected.[41] Surgical excision frequently is avoided with infection due to *M. tuberculosis* because infection usually extends into the mediastinum and responds to antituberculous therapy.

Actinomyces and *Nocardia* Species.

In cervicofacial actinomycosis, *Actinomyces israelii* causes a chronic, granulomatous suppurative infection of the soft tissues in and around the mandible. Although lymph nodes usually are not involved, chronic tissue induration can mimic chronic lymphadenopathy. Tissue destruction can be considerable without proper therapy.

The lymphocutaneous syndrome due to *Nocardia* spp. in children begins with a facial papular lesion followed by fever and an enlarged, tender, unilateral, submaxillary gland.[42] *N. brasiliensis* is the most common species causing the skin and lymph node cervicofacial syndrome. Lymphadenitis was associated with skin lesions in 58% of children in Texas with nocardiosis.[43] Lymphocutaneous nocardiosis can occur in healthy children, and an exhaustive search for an immunodeficiency is not necessary if there is a prompt response to trimethoprim-sulfamethoxazole therapy.

Calmette-Guérin Bacillus Vaccination.

When vaccination using Calmette-Guérin bacillus is given, painless enlargement of regional nodes (axillary, rarely cervical) can occur and presumably is due to multiplication of bacilli and formation of granulomas. Calcification or abscess formation with breakdown can occur, particularly in infants.[44] Rarely, regional adenitis can develop years after vaccination, especially if the individual becomes immunocompromised. Treatment is controversial, and spontaneous resolution of nonsuppurative lesions generally occurs without antimicrobial therapy in young children.[45]

Donovanosis.

Vertical transmission of *Klebsiella granulomatis* (granuloma inguinale or donovanosis) subacute cervical adenitis has also been described in two infants with concomitant otitis media and skin lesions. One child also had meningitis. Untreated vaginal ulcers were documented in both mothers during pregnancy[46,47] (see Chapter 139).

Noninfectious Causes of Lymphadenopathy

Kawasaki Disease.

Lymph node swelling is the least common of the principal diagnostic criteria of Kawasaki disease, occurring in 50% to 75% of patients. Lymphadenitis, one of the earliest manifestations, usually is unilateral and confined to the anterior triangle; the node is moderately tender. The enlarged node or mass of nodes usually is more than 1.5 cm in diameter and nonfluctuant, sometimes with overlying erythema. The ultrasound or computed tomography appearance of an acutely enlarged node due to Kawasaki disease differs from that of bacterial lymphadenitis and can be a useful diagnostic tool. In Kawasaki disease, suppuration does not occur, and edema of surrounding tissue is not pronounced.[48,49] Adenopathy of Kawasaki disease usually resolves early in the course of disease.

Periodic Fever, Aphthous Stomatitis, Pharyngitis, and Cervical Adenitis (PFAPA).

First described in 1987,[50] PFAPA usually affects children younger than 5 years. Bilateral, modestly enlarged and tender cervical nodes are typical during febrile episodes; other lymph nodes are not affected.

Sarcoidosis.

The most common physical finding in children with sarcoidosis is peripheral lymphadenopathy. Involved cervical nodes are enlarged bilaterally and are discrete, firm, and rubbery. More than 80% of children have involvement of the supraclavicular nodes; bilateral hilar adenopathy is almost always present, along with nonspecific symptoms and other multisystem manifestations.

Sinus Histiocytosis With Massive Lymphadenopathy (Rosai-Dorfman Disease).

Rosai-Dorfman disease is a rare non−Langerhans cell histiocytosis that manifests in the first decade of life with mobile, discretely and asymmetrically enlarged lymph nodes, initially usually located in the neck.[51] With progression, the nodes become massively enlarged bilaterally and are painless and adherent to surrounding tissues. Other nodal groups (e.g., axillary, inguinal, and hilar nodes) and extranodal sites can be involved. Systemic manifestations of fever, leukocytosis, neutrophilia, anemia, elevated inflammatory markers, and hypergammaglobulinemia frequently are present. Histopathologic analysis demonstrates florid follicular hyperplasia, marked histiocytic proliferation, and prominent plasmacytosis. Resolution occurs spontaneously after 6 to 9 months, but therapy may be required for extensive or progressive disease.

Histiocytic Necrotizing Lymphadenitis (Kikuchi-Fujimoto Disease).

Kikuchi-Fujimoto disease is a benign, rare entity of unknown etiology that manifests in older children with bilaterally enlarged, firm, painful cervical nodes, most often in the posterior cervical triangle, which are unresponsive to antibiotic therapy. Perinodal inflammation is common. Associated findings in 50% of patients include skin lesions, fever, leukopenia with atypical lymphocytosis, and an elevated erythrocyte sedimentation rate. Those with prolonged fever are more likely to develop leukopenia.[52] Splenomegaly, nausea, weight loss, and night sweats can be present. Nodal histology showing necrosis and exuberant histiocytic infiltration is characteristic but can be confused with that of malignant lymphoma. No other diagnostic test is available. Symptoms resolve in most patients a few days after excisional biopsy. Viral etiology is suspected based on a few reports of serologic studies suggesting EBV, CMV, human T-lymphotropic virus, HHV-6, and parvovirus B19 infection.[53] Kikuchi-Fujimoto disease also has been shown to occur in association with or preceding systemic lupus erythematosus in some cases. In most cases the prognosis for spontaneous resolution of Kikuchi-Fujimoto disease is excellent.[54,55]

Kimura Disease.

Kimura disease is a chronic, benign, but potentially disfiguring unilateral, localized cervical lymphadenopathy of Asians, most often males of Chinese or Japanese descent. Insidious onset of painless, subcutaneous nodules overlying the affected lymph nodes occurs. Eosinophilia and a marked increase in serum immunoglobulin E are present. Renal involvement can occur, with proteinuria present in 12% to 16% of cases.[56] Resection, irradiation, or corticosteroid therapy can be associated with recurrences.[57,58]

Neck Masses Not Involving Lymph Nodes

Tumors of the Head and Neck

The differential diagnosis of neck masses includes congenital cysts and sinuses, vascular malformations, salivary and thyroid anomalies, and benign and malignant neoplasms of nonsquamous origin.

Malignancy should be considered, particularly in older children with a painless, firm, cervical mass more than 3 cm in diameter that is fixed to the deep cervical tissues, has grown rapidly, or is located in the supraclavicular area or posterior triangle of the neck. Such masses can be multiple and can extend across the anterior and posterior triangles. The incidence of all pediatric cancer has increased in the past few decades; however, the incidence of pediatric neck masses over the same timeframe has increased at a greater rate. Teenagers 15 to 18 years old are the most frequently affected (39%), followed by children aged 4 years and younger (27%).[5]

Fifty percent of masses in the posterior triangle are malignancies, most of lymphoid origin. Fifty percent of all malignant neck masses in children are Hodgkin lymphoma or NHL; neuroblastoma is the next most common, accounting for 15%, followed by thyroid tumors. Soft tissue sarcomas, including primary rhabdomyosarcoma and carcinoma of salivary glands and the nasopharynx, also occur. Age is predictive of diagnosis; in children younger than 6 years, the most common malignancies, in order of decreasing frequency, are neuroblastoma, NHL, rhabdomyosarcoma, and Hodgkin lymphoma. In patients 7 to 15 years old, Hodgkin lymphoma and lymphosarcoma occur with equal frequency, followed by thyroid carcinoma, rhabdomyosarcoma, and parotid adenocarcinoma.

Soft tissue sarcomas manifesting in the neck are primary rhabdomyosarcoma and undifferentiated sarcomas. Rhabdomyosarcoma accounts for 18% of all solid carcinomas in children; of these, 36% manifest in the head and neck region, usually as an asymptomatic mass or with symptoms related to location.

Hodgkin lymphoma most commonly manifests as an asymptomatic cervical or supraclavicular mass. Upper cervical nodes are three to four times more likely to be involved than supraclavicular nodes. NHL is more likely to be associated with systemic symptoms, including fever and leukocytosis with pronounced neutrophilia, and cervical lymph node involvement, which can be unilateral and associated with massive swelling. Cervical adenopathy is a primary symptom in only 11% to 35% of patients with Hodgkin lymphoma, and extranodal head and neck masses are unusual.[59]

Congenital Cysts and Sinuses

Multiple congenital cysts and sinuses related to embryologic development can manifest as infection or as the sudden appearance of a mass as if infected.[60] Recurrence of a suppurative mass in exactly the same location should lead to evaluation for an underlying congenital lesion.[61] Table 17.4 delineates noninfectious causes of neck masses in children.

TABLE 17.4

Noninfectious Causes of Neck Masses[a]

Condition	Comments
CONGENITAL ANOMALIES	
Thyroglossal duct cyst	Most common congenital neck mass; discrete 1-cm midline nodule that may elevate with tongue protrusion; elective excision best; may contain only existing thyroid tissue
Second pharyngeal (branchial) cleft	Second most common congenital neck mass; anterior to upper or middle one third of sternomastoid muscle; external sinus opens anterior

anomaly	to sternal head of muscle; tract needs to be excised; cyst associated with lymphatic tissue
Cystic hygroma	Third most common congenital neck mass; occurs along jugular lymphatic chain in posterior supraclavicular fossa; failure of mesenchymal clefts to fuse; varies from few centimeters to massive collar-like lesions; may extend into mediastinum
Dermoid or epidermoid cysts	Midline, deep to mylohyoid muscle; soft, fluid-filled midline mass; may elevate with tongue protrusion; contain caseous material or epithelial debris
NONLYMPHOMATOUS MALIGNANCIES	
Neuroblastoma	Second most common malignant neck mass in children (first in younger children)
Thyroid cancer	Third most common neck malignancy (first in 11–18 years); high incidence of malignancy in thyroid nodules; prompt biopsy required
Rhabdomyosarcoma	Most common nasopharyngeal malignancy in children
Nasopharyngeal carcinoma	Cervical adenopathy often initial and only symptom; arises most often in fossa of Rosenmüller
Parotid tumors	Vascular anomalies most common; asymptomatic node may be malignant and should be excised
MISCELLANEOUS	
Sternocleidomastoid tumor	Fibrous mass within muscle; detected at 2–4 weeks of age in 0.4% of infants; head turned away from mass; ipsilateral facial hypoplasia
Sinus histiocytosis with massive lymphadenopathy (Rosai-Dorfman disease)	Bilateral, painless cervical nodes; generalized lymphadenopathy may develop; systemic manifestations include fever and hypergammaglobulinemia; self-limited
Giant lymph node hyperplasia (Castleman disease)	Asymptomatic lymphadenopathy in mediastinum or neck; systemic symptoms include fever and hypergammaglobulinemia; surgical removal curative (see Chapter 18)
Histiocytic necrotizing lymphadenitis (Kikuchi-Fujimoto disease)	Asymptomatic cervical or generalized adenopathy; skin lesions, fever, and leukopenia; spontaneous resolution; recurrences possible
Kimura disease	Benign, chronic, unilateral lymphadenopathy; adjacent subcutaneous nodules, peripheral eosinophilia and increased serum immunoglobulin E, proteinuria and renal involvement possible

[a] For review of lymphomas, see Chapters 16 and 18.

Branchial Cleft Cysts and Sinuses.

During the fifth week of embryologic development, four endodermal pharyngeal pouches fuse with four ectodermally derived clefts and are obliterated. Rarely, they are not completely obliterated, and persistence of the cleft can result in a cystic mass or sinus tract that is prone to infection. Persistence of the first pharyngeal cleft results in a sinus tract opening just behind the ramus of the mandible. Cystic components of the tract, which extends to the external ear canal, often are more extensive than is apparent clinically. Persistence of the second cleft is most common, the opening of which is just anterior to the sternal attachment of the SCM muscle. The unseen tract extends the length of the SCM muscle, beginning at the tonsillar bed. Cysts, with potential for acute enlargement, can occur anywhere along the length of the tract. Anomalies of the second and third cleft are indistinguishable. Because the thymus also is derived from the third cleft, thymic duct remnants can be seen as soft, fluctuant, mobile paratracheal masses low in the neck. Surgery usually is required to remove the sinus tract or cyst to prevent recurrences.

Midline Sinuses and Cysts.

Dermoid or epidermoid cysts are embryologic defects in fusion. They occur as painless, soft, fluid-filled midline masses.

Thyroid tissue originates embryologically at the base of the tongue and descends the thyroglossal duct to its usual site anterior to the proximal end of the trachea. Although the tract usually is obliterated, cysts can form along its course, appearing as 1-cm midline nodules. Retaining attachment to the base of tongue, such cysts elevate on tongue protrusion. It is important to determine the presence and position of thyroid tissue, because cysts may contain the only functional gland. Nodules within the thyroid gland have a high incidence of malignancy in children. A thyroid mass in the neonate most often is a congenital goiter or a teratoma.

Lymphangiomas.

In the sixth embryologic week, clefts develop in the cervical mesenchyma, which subsequently fuse to form lymph channels and lymph nodes. Sequestration, or failure to communicate with the rest of the lymphatic system, leads to tumor-like masses of lymph channels most commonly found along the external jugular chain of lymphatics in the lateral cervical region. Lymphatic masses vary in size from a few centimeters to massive collar-like lesions with extension into the mediastinum. In the larger lesions, lymphatic channels dilate into cystic spaces, and the lesion is called a *cystic hygroma*. Most cystic hygromas are posterior to the sternomastoid muscle in the supraclavicular fossa. Sixty-five percent are present at birth and gradually increase in size as a result of obstructed flow or bleeding; the remainder almost always appear before age 2 years (Fig. 17.6).

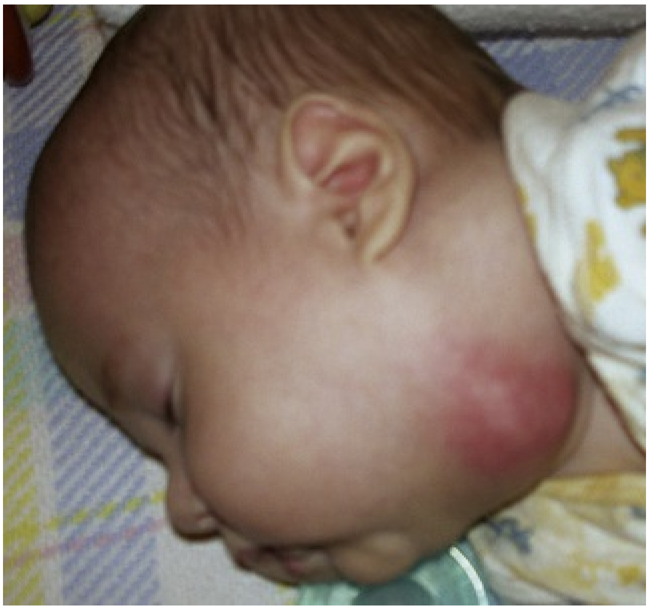

FIGURE 17.6 Cystic hygroma in a 2-month-old child, infected secondarily with group B *Streptococcus*.

Salivary and Thyroid Gland Masses

Parotid Gland Masses.

Parotid tumors are rare. The most common parotid masses are vascular anomalies, usually capillary hemangiomas and rarely cavernous hemangiomas. Large cavernous hemangiomas can disfigure and destroy tissue, whereas capillary hemangiomas usually resolve by the age of 4 or 5 years without any permanent findings. Parotid gland enlargement in childhood can result from calculus formation or recurrent sialectasia, in which case the parotid gland becomes rubbery, firm, and tender but has no signs of inflammation. Parotid infections are discussed in Chapter 25.

Thyroiditis.

Infection of the thyroid gland is rare but potentially is life threatening. Infection can arise by the hematogenous route or directly from an adjacent fascial space infection, from a patent foramen cecum and infected thyroglossal duct cyst, or from anterior esophageal perforation. Suppuration usually results from infection of pyriform sinus fistula or thyroglossal duct remnant. The most common aerobic pathogens are *S. aureus,* group A streptococci, pneumococci, and viridans streptococci. Anaerobic bacteria also are isolated, with the most common being gram-negative bacilli including *Prevotella* spp. and *Peptostreptococcus* spp. Other pathogens are *Haemophilus influenzae, Eikenella corrodens,* and *Actinomyces* spp., with rare reports of enteric gram-negative bacilli, mycobacteria, and fungi.[62,63]

History and physical examination identify acute onset of fever, chills, sore throat, dysphagia, hoarseness, and an extremely tender, red, warm, and enlarged gland. Involvement can be unilateral or bilateral; pain can be referred to the ear or chest. Results of thyroid function tests usually are normal. Laboratory investigation of thyroiditis should include ultrasonography, radionuclide scan, or computed tomography to detect paratracheal extension; needle aspiration is performed for diagnostic microbiology. With prompt and aggressive therapy, complete resolution without abscess formation is expected.

Subacute (de Quervain) thyroiditis is a poorly defined, self-limited condition characterized by an insidious onset with tenderness and marked induration of the gland. The sedimentation rate is high, and biopsy reveals acute and chronic inflammation with granulomatous changes. In most cases, the cause is a virus, such as mumps virus, influenza virus, enterovirus, adenovirus, echovirus, EBV, or, rarely, St. Louis encephalitis virus.[63] Mild and transient manifestations of hypermetabolism and elevated thyroid hormone levels can be present. Differentiation from bacterial thyroiditis can be difficult.

Diagnostic Approach to Cervical Lymphadenopathy

The assessment and specific evaluation and management of cervical lymphadenopathy and lymphadenitis are directed by integration of the history and initial examination (Table 17.5). In young infants with acute unilateral involvement and systemic manifestations, causative agents can be expected to be *S. aureus,* group B *Streptococcus,* or gram-negative organisms. Blood, as well as aspirate of the node or cellulitis, is obtained for culture. Examination of cerebrospinal fluid should be considered in young infants if the etiology is group B *Streptococcus*. Isolated finding of discrete small cervical nodes in a healthy infant is likely to be normal (see Table 17.1). Associated findings may lead to evaluation for congenital infection in other patients.

TABLE 17.5

Mode of Onset and Characteristics of Lymph Nodes Infected by Selected Organisms

	Mode of Onset		Characteristics		
Pathogen	**Acute**	**Subacute/Chronic**	**Suppuration**	**Cellulitis**	**Generalized Adenopathy**

++++, Characteristic; +++, frequently associated; ++, occasionally associated; +, rarely associated; –, not known to be associated.

The older child with bilateral, soft, discrete, minimally tender, and minimally enlarged (<2 cm) nodes high in the neck who has had respiratory tract symptoms and fever usually has a viral infection, or may have streptococcal pharyngitis or *M. pneumoniae* infection. In roseola, rubella, adenoviral, or enteroviral infections, cervical adenopathy is frequently in the suboccipital, posterior auricular, or superficial posterior cervical areas (Table 17.6).

++++, Characteristic site of adenopathy; +++, additional site, often associated; ++, occasional site; +, rare site; –, not described.

If nodes are large and minimally tender, with no overlying cellulitis, mononucleosis due to EBV or CMV is likely. For protracted or unusual cases, sarcoidosis, Kikuchi-Fujimoto and Rosai-Dorfman diseases are considered.

When acute unilateral or bilateral adenopathy is associated with an obvious site of infection, diagnostic studies are focused on the site. Obvious sites of infection include herpes simplex ulcerations, infected abrasions, scalp infections, animal bites or scratches, and conjunctival granulomas.

Acutely inflamed, unilateral, tender large nodes with associated periadenitis and cellulitis, fever, and constitutional symptoms, often with poor node definition and torticollis, are usually due to *S. aureus* or *S. pyogenes* in the young child[64] (see Tables 17.3 and 17.5). In older children and adolescents, a dental focus with resulting anaerobic infection should be considered. Failure to respond to antibiotic therapy after 48 hours leads to evaluation for antimicrobial resistance, an abscess or a more unusual cause such as Kawasaki disease, and infected or uninfected congenital cysts and sinuses.

The most challenging problem is the patient with a unilateral, asymptomatic, initially noninflamed, nontender, firm node of acute or subacute onset. Some such nodes become fluctuant and develop the characteristic findings of cat-scratch disease or nontuberculous mycobacterial disease, whereas others do not change over time.

It is important to identify toxoplasmosis, tuberculosis, and lymphoma or another malignancy as soon as possible to initiate appropriate therapy if indicated. Accurate measurements of the size and consistency of such nodes should be performed once or twice a week to determine whether malignancy should be considered. The presence of systemic symptoms, hepatosplenomegaly, pneumonia, or mediastinal adenopathy is suggestive of tuberculosis or malignancy.

Guidance for biopsy of lymph nodes to rule out a malignancy is provided in Box 17.2. If an excisional biopsy is performed and nonspecific hyperplasia is reported, the patient must be followed carefully because 25% of patients with such findings are ultimately found to have a lymphoreticular malignancy.

Box 17.2

Settings That Prompt Early Consideration of

Biopsy of Enlarged Cervical Lymph Node to Rule Out Malignancy

Site

Supraclavicular

Posterior cervical (particularly with extension across sternomastoid muscle to involve anterior and posterior triangles)

Deep to fascia

Size

>2 cm diameter

Continued enlargement after 2 weeks

No significant decrease in size after 4–6 weeks

Not normal in size after 8–12 weeks

Consistency

No inflammation

Nontender (unless rapidly enlarging)

Firm, rubbery, or matted (may be fixed to underlying structures)

Ulceration

Potential Local or Systemic Spread

Mediastinal or generalized adenopathy

Bone marrow involvement

Fever, weight loss, hepatosplenomegaly

Recurrent epistaxis, progressive nasal obstruction, facial paralysis, or otorrhea

No Evidence to Support an Infectious Etiology

Negative results of evaluation for infectious causes

No response to empirically chosen antibiotics

Needle Aspiration

Needle aspiration of the infected node is a valuable diagnostic tool for acute and subacute lymphadenitis and also can be therapeutic. In 60% to 90% of patients with acute cervical lymphadenitis in whom needle aspiration is performed for bacterial and mycobacterial culture, an etiologic agent is recovered.[6,7,13,65] The procedure is safe and easy to perform and has no serious complications. Controversy exists as to whether a persistently draining fistula is precipitated by aspiration if the lymphadenitis is due to mycobacterial infection. The preponderance of data suggests that aspiration (unlike incision and drainage) is not contraindicated and is greatly useful to direct definitive therapy. Because tuberculous and nontuberculous diseases are difficult to distinguish clinically, fine-needle aspiration is a useful diagnostic tool if *M. tuberculosis* exposure is possible. Rapid identification by molecular methods also is being used as a diagnostic tool using needle aspiration samples.[66,67]

The specimen is obtained from the largest and most fluctuant node. If no material is aspirated, saline is injected into the node and repeat aspiration performed. Gram and acid-fast stain should be performed, and the specimen should be inoculated onto media for growth and isolation of anaerobic and aerobic bacteria, fungi, and mycobacteria. If no visible specimen is obtained, the needle and syringe can be flushed into a blood culture flask.

Lymph Node Biopsy

If the diagnosis remains in doubt and the enlarged lymph node fails to regress, enlarges further, is hard, or is fixed to adjacent structures, biopsy should be performed. An accelerated schedule for biopsy is appropriate in the presence of persistent fever or weight loss (in the absence of confirmed diagnosis) or if firm lymph nodes are found in the posterior cervical triangle or supraclavicular area (if *M. tuberculosis* and *B. henselae* are excluded). These settings are associated with greater possibility of malignancy.

Excisional biopsy (to establish lymph node architecture and complete histologic character) is preferred to incisional biopsy of lymph nodes, although some studies support the use of fine-needle aspiration as an initial diagnostic mechanism; negative or nonspecific findings do not exclude malignancy.[68,69] Yield from biopsy is maximized through careful choice of tissue site and proper handling of resected tissue. Generally, the largest, firmest nodes should be excised. Whenever possible, more than one node should be obtained. When several groups of nodes are involved, biopsy specimens taken from the lower neck and supraclavicular area (or a region other than the neck) have higher diagnostic yield than those taken from high cervical nodes. If EBV or toxoplasmosis is expected, biopsy is carefully considered because of the difficulty of discrimination of such diseases from malignancy and the ability to confirm both diagnoses by serologic testing. If lymphoma is suspected, needle biopsy or frozen section is unreliable for excluding the diagnosis. When nontuberculous mycobacterial infection is suspected and surgery is required for diagnosis and therapy, excisional dissection of deep nodes may be necessary. The individual situation dictates specific evaluations of excised tissue, but evaluation commonly consists of flow cytometry; special stains, including Giemsa, periodic acid–Schiff, methenamine silver, and Warthin–Starry silver stains; and, in selected cases, testing by in situ hybridization, PCR, or electron microscopy. Culture for facultative and anaerobic bacteria, mycobacteria, and fungi is appropriate.

Many reactive processes simulate malignant histology and may make definitive diagnosis impossible. Examples are dysregulated inflammatory responses as with rheumatoid arthritis, phenytoin-induced adenopathy, dermatopathic adenitis, and infections such as toxoplasmosis and EBV mononucleosis. A thorough history and a second series of evaluations, including serologic tests, are essential for making a correct diagnosis of these cases.

Management

Initial Therapy

Children with bilaterally enlarged cervical lymph nodes (<3 cm in size) that are not erythematous or exquisitely tender are observed without evaluation or therapy. If the initial findings are typical of acute bacterial lymphadenitis (unilateral node, >2 to 3 cm, erythematous, and tender) without systemic symptoms, empiric therapy is given for *S. aureus* and *S. pyogenes* infection unless the course or findings are typical for *S. pyogenes* (Table 17.7). Therapy usually is given for 10 days or at least 5 days beyond resolution of acute signs and symptoms, whichever is longer. Knowledge of local resistance patterns of *S. aureus* is important when choosing empiric therapy. Antimicrobial resistance or alternative pathogens should be considered if empiric antimicrobial therapy fails. If a primary focus of infection is identified elsewhere, the mode and duration of therapy are directed in reference to that site as well. Impetigo and other skin infections usually are caused by *S. aureus* and *S. pyogenes.* Dental or periodontal disease leads to lymphadenitis due to anaerobic bacteria. A culture should be obtained from suppurative sites whenever possible. Aspiration of the inflamed site should be performed if moderate to severe adenitis with cellulitis and constitutional symptoms is present or if no improvement occurs after 48 to 72 hours of therapy. In the latter instance, additional diagnoses are considered, including viral infection, Kawasaki disease, nontuberculous mycobacterial infection, and more unusual causes of adenitis. If cat-scratch disease is suspected, *Bartonella*-specific antimicrobial therapy is given if a node is larger than 3 cm, in an attempt to avoid abscess formation (see Chapter 160).

TABLE 17.7

Treatment of Acute Bacterial Cervical Lymphadenitis

Presumed Pathogen and Setting	**Empiric Therapy (Consult Local Antibiogram)**	**Route/Duration**	**Diagnostic Tests**
STAPHYLOCOCCUS AUREUS* OR *STREPTOCOCCUS PYOGENES			
No prominent systemic symptoms, cellulitis, or suppuration	Amoxicillin-clavulanate, cephalexin, or clindamycin (TMP-SMX if MRSA known, not for *S. pyogenes*)	PO/10 days or 5 days past resolution of symptoms, whichever is longer	Routine culture (+ PCR for MRSA)
With cellulitis, marked	Nafcillin, cefazolin, or clindamycin; vancomycin	IV/10 days or 5 days past resolution of	Routine culture (+ PCR for MRSA)

enlargement, moderate or severe symptoms	or clindamycin for MRSA	symptoms, whichever is longer. Consider PO after clinical improvement	
With suppuration	Needle aspiration if no improvement after 48 hours, consider parenteral antibiotics as above and incision and drainage	IV/10 days or 5 days past resolution of symptoms, whichever is longer. Consider PO after clinical improvement	Routine culture (+ PCR for MRSA)
GROUP B *STREPTOCOCCUS* OR *STAPHYLOCOCCUS AUREUS*			
Infant <2 months with cellulitis with or without systemic symptoms or adenitis	Nafcillin or oxacillin	IV/10–14 days	Routine culture (+ PCR for MRSA)
	Vancomycin if MRSA rates high (evaluate for meningitis if group B *Streptococcus*)		
ANAEROBIC BACTERIA			
Associated dental or periodontal disease, bull neck	Clindamycin or penicillin plus metronidazole	PO or IV, depending on anatomic locations and severity of disease	Anaerobic culture
	(Alternative piperacillin/tazobactam or carbapenem if severe disease)		
BARTONELLA HENSELAE			
Fluctuant or draining node; systemic manifestations	Needle aspiration of node; consider use of azithromycin, rifampin, ciprofloxacin, TMP-SMX, or gentamicin (see Chapter 160)	PO, IV/optimal duration not known	Serologic analysis, PCR, granulomas on tissue, Warthin-Starry silver stain of tissue
NONTUBERCULOUS *MYCOBACTERIUM*			
TB ruled out; node not draining	Excision of node or see Chapter 135		TST, mycobacterial culture, tissue PCR, granulomatous reaction
Mycobacterium tuberculosis	See Chapter 134		TST, mycobacterial culture, tissue PCR, granulomatous reaction, Interferon-γ release assays
FRANCISELLA TULARENSIS			
Acute onset, fever; diagnosis reasonably certain	Streptomycin (gentamicin/amikacin) Alternative: ciprofloxacin, doxycycline; see Chapter 171	IM, IV/10 days or longer for severe illness	Serologic analysis, PCR, culture of blood or tissue (alert laboratory personnel with clinical suspicion)
PASTEURELLA MULTOCIDA			
Onset within 24 hours of animal bite	Amoxicillin-clavulanate or nafcillin until diagnosis confirmed; then penicillin	PO, IV depending on severity/7–10 days for local infections and 10–14 days for severe infections	Routine culture

IM, intramuscular; IV, intravenous; MRSA, methicillin-resistant *Staphylococcus aureus*; PCR, polymerase chain reaction; PO, oral; TB, tuberculosis; TMP-SMX, trimethoprim-sulfamethoxazole; TST, tuberculin skin test.

Routine antituberculous therapy generally is ineffective for nontuberculous mycobacterial infections. In cases in which removal of the node is not advised (e.g., because of size or proximity to the facial nerve), combination therapy for NTM generally is given (see Chapter 135).

Patients with marked lymph node enlargement, moderate to severe systemic symptoms, and cellulitis frequently require parenteral therapy for the first several days. This route provides a higher concentration of drug in inflamed tissue, halts bacteremia if present, and may promote more rapid localization. Although a decrease in fever, inflammation, and tenderness is expected within 48 to 72 hours after appropriate treatment of bacterial lymphadenitis, lymph node regression may be slow, requiring 4 to 6 weeks, and suppuration despite appropriate therapy is not unusual.

Abscess Drainage

Ultrasonography or computed tomography can be helpful in cases in which abscess is suspected in the absence of fluctuation on physical examination.[59] For abscesses due to *S. aureus* or *S. pyogenes*, incision and drainage are the procedures of choice. Needle aspiration can be therapeutic. For abscesses from suspected mycobacterial or *Bartonella* infection, aspiration (with an 18- or 19-gauge needle) initially is preferred to avoid fistula formation. Installation of saline may facilitate aspiration when pus is very thick. Surgical excision is required infrequently for cat-scratch disease.

Surgical Excision and Long-Term Therapy

Surgical excision is the most effective treatment for nontuberculous mycobacterial cervical adenitis.[37,70,71] Excision of the largest and necrotic mass or masses usually is adequate because the remaining adenopathy resolves spontaneously over ensuing months. Excision of all affected nodes (especially as documented by imaging studies) requires extensive and difficult surgery and is not warranted as a first procedure; adjunctive antimicrobial therapy usually is given. When infection has ruptured into soft tissue, resection of inflamed overlying skin and sinus tracts, followed by primary closure without leaving a drain, is advocated. A decision to begin combination therapy for *M. tuberculosis* infection is based on the clinical setting and tuberculin skin test results. The clinical response of *M. tuberculosis* infection to antituberculous therapy usually is rapid, with resolution of symptoms and marked regression of the lymph nodes within 3 months; prolonged therapy is required. *Actinomyces* infections of the neck require very prolonged antimicrobial therapy; osteomyelitis of the jaw may require aggressive debridement as well.

Complications

Complications of pyogenic neck infections, such as mediastinal abscess, purulent pericarditis, thrombosis of the internal jugular vein, and pulmonary emboli or disseminated septic emboli, have become uncommon since the availability of effective antimicrobial therapy. *Fusobacterium* spp. infection is an exception. Rapid progression or failure to treat adenitis due to *S. aureus* or *S. pyogenes* can result in cellulitis, bacteremia, septicemia, or toxin-related symptoms. Poststreptococcal acute glomerulonephritis occurs occasionally.

Mediastinal and Hilar Lymphadenopathy

Mary Anne Jackson, J. Christopher Day

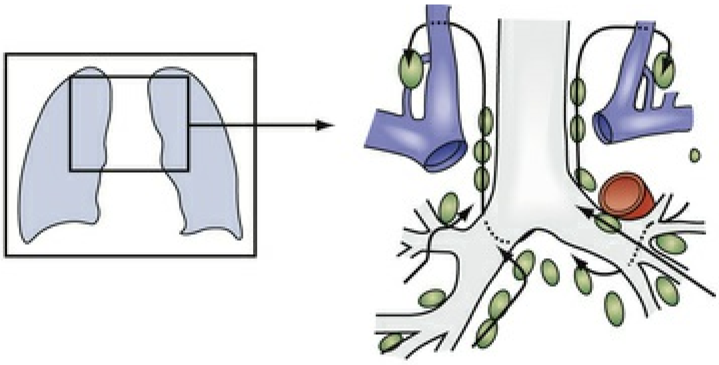
Anatomy of the Mediastinum

The mediastinum is the space between the pleural cavities that contains the heart and all chest viscera except the lungs. Consisting of loose areolar tissue and organs, the mediastinum is more a potential space than an actual body cavity. It is bounded laterally by the parietal pleurae, anteriorly by the sternum, posteriorly by the ribs and paravertebral gutters, superiorly by the thoracic inlet, and inferiorly by the diaphragm. The *anterior mediastinum* contains everything anterior and superior to the heart, including the thymus, aortic arch and its major branches, innominate veins, and lymphatic tissue (nodes and vessels). Most masses here are of thymic origin—teratomas, lymphomas, or angiomatous tumors. The *middle mediastinum* is triangular with the apex at the fourth thoracic vertebra. It contains the heart, pericardium, trachea, pulmonary hilar and mediastinal lymph nodes and vessels, and phrenic and vagus nerves. Masses in this compartment usually are infectious or are malignant lesions of lymph nodes. The *posterior mediastinum* extends from the first rib to the diaphragm, behind the heart and lung roots. It contains the esophagus, descending aorta, paravertebral lymph nodes, lower portion of the vagus nerve, and sympathetic nerve chains. Neurogenic tumors and duplication cysts are the most common lesions encountered.

Although the delicacy of mediastinal tissue planes offers little resistance to the spread of disease between compartments, tumors and inflammation tend to extend within compartments. Infections within the mediastinum are relatively uncommon, but their proximity to many vital structures makes accurate diagnosis essential.

Lymphatic Drainage of the Lungs and Pleura

As shown in Fig. 18.1, lymph from the thoracic viscera (heart, pericardium, lungs, pleura, thymus, and esophagus) traverses one of three possible sets of nodes before entering the thoracic duct or right lymphatic duct. Anterior mediastinal nodes are located anterior to the aortic arch, innominate veins, and large arterial trunks leading from the aorta. They receive afferents from the thymus and pericardium, the sternal nodes, and the thyroid gland.



Lymph drainage patterns

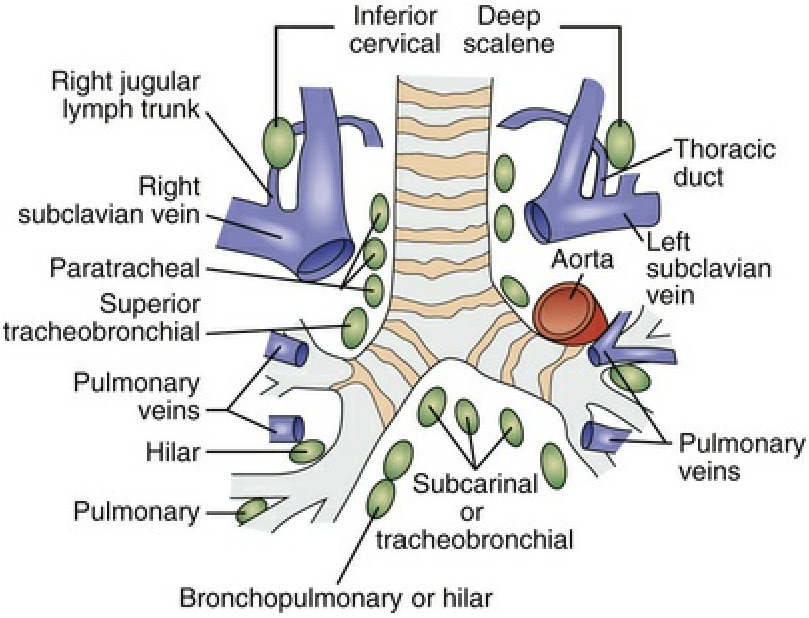


FIGURE 18.1 Lymphatic drainage of the thorax.

Posterior mediastinal nodes lie dorsal to the pericardium and adjacent to the esophagus and descending aorta. They receive afferents from the esophagus, dorsal pericardium, diaphragm, and convex surface of the liver. Middle or mediastinal nodes drain the lungs and pleura. Lymphatic drainage of the lungs is composed of superficial and deep plexuses. The superficial plexus lies beneath the visceral pleura. Lymph flows around the border of the lung to enter the bronchopulmonary (hilar) nodes. The deep plexus accompanies branches of the pulmonary vessels and ramifications of the bronchi throughout the lungs.

Lymphatic drainage of the lung passes through four sets of lymph nodes (Table 18.1). Intrapulmonary lymph nodes are located within the lung, chiefly at the bifurcations of the larger bronchi. Bronchopulmonary or hilar nodes are located at the pulmonary hilus at the site of entry of the main bronchi and vessels. Tracheobronchial nodes are divided into superior and inferior groups. The superior group lies in the obtuse angle between the trachea and bronchi on both sides. The inferior, or subcarinal, group lies under the carina at the tracheal bifurcation. The fourth group, the tracheal or paratracheal nodes, lies beside and somewhat anterior to the trachea. A fifth group of lymph nodes of importance in the drainage of the lungs is the inferior deep cervical (scalene or supraclavicular) chain, which is located over the lower portion of the internal jugular vein, just above the clavicle and usually under the scalenus anterior muscle. The apical pleurae drain directly to these deep cervical nodes, as do the paratracheal chains. A finding of supraclavicular lymphadenopathy should lead to investigation for intrathoracic or intra-abdominal pathology.

TABLE 18.1
Lymphatic Drainage of the Lung and Pleura

Lymph Node Group	Areas Drained
Intrapulmonary	Pulmonary vessels, bronchi, and parenchyma
Hilar (bronchopulmonary)	Intrapulmonary nodes and superficial plexus of visceral pleural lymphatics
Tracheobronchial: superior and inferior (subcarinal)	
Right side	All hilar nodes of right lung and hilar nodes of left lower lobe and lingula
Left side	Left upper lobe hilar nodes
Paratracheal	
Right side	Right tracheobronchial nodes
Left side	Left tracheobronchial nodes
Supraclavicular	
Right side	Right apical pleura, right paratracheal nodes, head, neck, arms, and upper thorax
Left side (Virchow node)	Left apical pleura, left paratracheal nodes, intra-abdominal nodes, head, neck, arms, and upper thorax

Ultimately, all lymph from the lungs and pleurae reaches the tracheobronchial and paratracheal lymph nodes. Generally, lymph from the lungs flows from left to right, a probable explanation for the preeminence of right upper paratracheal and supraclavicular lymphadenopathy in infectious pulmonary processes, particularly tuberculosis. Lymph from the left lower lobe (and usually also the lingula) flows from the hilar nodes to the lower tracheobronchial nodes, and then to the right paratracheal nodes. Lymph from the right hilar nodes travels to the right paratracheal nodes (see Table

18.1).

Lymph vessels from the paratracheal nodes join with lymph trunks from the anterior mediastinum to form the right and left bronchomediastinal trunks. These trunks then join with the lymphatic trunks from the supraclavicular nodes to form the right lymphatic duct and left thoracic duct.

Epidemiology

At least one third of all mediastinal masses occur in children younger than 15 years; one half of such masses are symptomatic. Among children with mediastinal masses, 50% who present with symptoms of airway compression have malignant tumors, whereas 90% of those who have noncompressive symptoms have nonmalignant conditions. The greater proportion of symptomatic masses in children compared with adults may be due to smaller thoracic size, resulting in symptoms of compression, or to a higher frequency of malignant lesions.[1] The overall incidence of tumors (excluding metastatic disease) and cysts in the mediastinum is 1 per 100,000 people.

In a series of biopsies of only anterior and middle mediastinal masses in children (thus excluding neurogenic tumors), 1% to 57% are reported to be due to histoplasmosis. This extreme variance in rate is due to prevalences of *Histoplasma capsulatum* in the geographic areas in which studies are done. For example, at St. Jude Children's Research Hospital in Memphis, histoplasmosis was a relatively common complication in children with cancer, and a reason for referral of children without cancer.[2] Fever with pulmonary infiltrates (frequently nodular) and hilar or mediastinal mass and lymphadenopathy were the usual presentation. Blastomycosis, coccidioidomycosis, and tuberculosis also are associated with infectious mediastinal disease. A variety of other pathogens, including *Pneumocystis jirovecii* and *Mycoplasma* spp., can lead to mediastinal lymphadenitis associated with pulmonary infiltrates. Cysts and tumors predominate as the cause of posterior mediastinal lymphadenopathy (Table 18.2). Generally, neurogenic tumors are the most common cause of mediastinal masses; lymphomas are second, and germ cell tumors are third in frequency.

TABLE 18.2

Relative Frequencies of Noninfectious Mediastinal Masses in Children[a]

	Study			
	Silverman and Saleiston[31]	**Filler et al.[32]**	**Woods et al.[15]**	**Gaebler et al.[33]**
Number of children	437	429	68	37
FREQUENCY OF MASS (%)				
Neurogenic tumor	40	33	—	—
Lymphoma	18	14	68	43
Leukemia	—	—	17	—
Germ cell tumor	11	9.8	—	—
Mesenchymal tumor	7	6.8	—	—
Bronchogenic cyst	7	7.5	—	—
Lymph node infection	—	4.4	9	57
Other cysts or malignancy	14	25	6	—

[a] Anterior and middle mediastinal masses only.

Characteristics of Lymphadenopathy

Lymph nodes are readily identifiable on computed tomography (CT) and can be categorized according to size, shape, coalescence, replacement by tumor mass, presence of calcium, abscess cavities, and parenchymal lung involvement. Most authorities use a 10-mm diameter as the upper limit of normal size for lymph node.[3,4] Mediastinal lymph nodes larger than 20 mm virtually are always abnormal; this statement may not be true for hilar nodes. Mediastinal nodes have the potential to become much larger than any other nodes in the body.

Densely calcified bilateral nodes are typical of histoplasmosis and, occasionally, of blastomycosis, coccidioidomycosis, or sarcoidosis. Unilateral densely calcified nodes are typical of prior or late-diagnosed tuberculosis. Benign mediastinal tumors also can be calcified (i.e., teratoma, cystic thymoma, and thyroid adenoma). Childhood lymphomas can cause bilateral hilar adenopathy but usually do not become calcified until after therapy.

In general, mediastinal mass lesions require a tissue diagnosis. Situations in which a biopsy may not be necessary include (1) certain granulomatous lesions that show dense calcification and are not increasing in size, as shown by consecutive imaging studies; (2) lymphomatous lesions diagnosed by biopsy of tissue outside the thorax; and, most important, (3) tuberculosis or histoplasmosis, which should be confirmed with other diagnostic testing.

Clinical Manifestations

Mediastinal lymphadenopathy frequently is asymptomatic until compression or erosion through a mediastinal structure occurs. Table 18.3 delineates findings associated with mediastinal disease. Respiratory symptoms result from airway obstruction or erosion. If the obstruction is significant enough, distal obstructive emphysema, atelectasis, pneumonia, or chronic, recurrent respiratory tract infections can result. Obstruction of the superior vena cava is a rare complication most commonly associated with rapidly growing malignant mediastinal tumors. The superior vena cava is particularly vulnerable to obstruction because of its thin wall, low intravascular pressure, and confinement by lymph nodes and other rigid structures. Older children with mediastinal masses may describe feeling intrathoracic discomfort or pain, which probably is due to pressure on intercostal nerves or pleura. Vertebral erosion secondary to posterior mediastinal tumors can cause a boring, interscapular pain. Most children with mediastinal disease caused by histoplasmosis present with chest pain or cough.

TABLE 18.3

Symptoms of Compression Resulting From Mediastinal Adenopathy

Structure	Symptom or Sign
Airway	Cough, wheezing; recurrent respiratory infections, bronchitis, atelectasis, unresolved pneumonia; hemoptysis; chest pain, sudden death
Esophagus	Dysphagia (interruption of peristalsis); hematemesis (fistula formation)
Superior vena cava	Dilation of collateral veins of the neck and upper thorax; chemosis of conjunctiva; edema of face, neck, upper chest, and arm; cyanosis; headaches, visual disturbances; epistaxis, tinnitus
Lymphatic channels	Pleural effusion
Recurrent laryngeal nerve	Hoarseness, inspiratory stridor (paralysis of vocal cord)
Phrenic nerve	Paralysis of left diaphragm

Sympathetic ganglia	Horner syndrome
Vertebrae, ribs	Pain secondary to bony erosion; symptoms of spinal cord compression

The finding of mediastinal widening, regardless of symptoms, leads to evaluation by CT. The diagnosis of lymphoma is considered first. If granulomatous lung disease is present, the diagnosis of tuberculosis is considered, as is histoplasmosis in endemic regions. History of travel, foreign birth, consumption of unpasteurized milk, or farm or bird exposure is sought.

Diagnosis

Historically, the differential diagnosis of mediastinal masses evident on chest radiograph was considered according to location within one of the four mediastinal compartments. Use of CT has largely supplanted the need for this classification because distinct tissue groups are now defined: fat, lymph nodes, vessels, airways, thymus, esophagus, and paraspinal tissues.

Imaging Studies

CT is the imaging study of choice for children with mediastinal mass. Unenhanced CT augments recognition of calcification. CT with administration of contrast material is useful to define anatomy better and distinguish vessels from lymph nodes. Identification of a solid, homogeneously enhancing soft tissue mass distinguishes lymphoma from cavitating lesions of histoplasmosis and tuberculosis, which are peripherally enhancing with low attenuation centrally. With the widespread use of multidetector helical CT, multiplanar imaging now is routine and allows definition of mediastinal structures in all planes. Magnetic resonance imaging (MRI) is required infrequently to evaluate the mediastinum because most lesions are visualized well on multidetector helical CT. In addition, MRI usually requires sedation (which can be dangerous in the presence of intrathoracic mass) and cooperation of the child to hold the breath (lest there be motion artifact). MRI is used for specific problem solving, such as evaluation of soft tissue masses of the chest wall, and when neurogenic lesions are suspected, to evaluate extension into the spinal canal.

Although CT and MRI are highly sensitive in detecting enlarged lymph nodes, neither reliably distinguishes between benign and malignant causes. Both can show displacement or compression of trachea or esophagus, but neither distinguishes invasion. MRI has the limitation of not being able to demonstrate calcium and is highly sensitive to motion (breathing or heart contraction) artifact.

Tissue Diagnosis and Biopsy

In general, mediastinal mass lesions require a tissue diagnosis because of likely causes and their proximity to vital structures. In some cases, diagnosis can be made without obtaining mediastinal tissue. Supraclavicular nodes (whether enlarged or not) or other enlarged extrathoracic nodes can provide diagnostic tissue. In one half of children with mediastinal malignancy, at least one lymph node in the cervical, supraclavicular, or infraclavicular or axillary area is larger than 2 cm and can be biopsied. Tissue biopsy from other sites, along with serologic testing, can confirm sarcoidosis. Bronchoscopy with bronchoalveolar lavage or gastric aspirates may identify an infectious cause.

Infectious Causes

Table 18.4 shows differentiating features of the causes of mediastinal lymphadenopathy. Mycobacteria and the endemic fungal organisms, *Histoplasma* and *Coccidioides,* commonly cause hilar and mediastinal adenopathy. Although mediastinal infection without significant pulmonary infection is rare, the degree of adenopathy frequently is disproportionate to degree of parenchymal involvement. Pneumonia due to *Mycoplasma pneumoniae, Bartonella henselae, Yersinia enterocolitica,* or *Francisella tularensis* can be associated with hilar adenopathy, as can bronchiectasis and cystic fibrosis. Adenopathy is rare in other acute bacterial and viral pneumonias.

TABLE 18.4

Causes of Mediastinal Lymphadenopathy

[a] After treatment.

++, Frequent; +, occasional; ±, rare, consider under special circumstances.

Bacterial Causes

Mycobacterium tuberculosis.

Primary pulmonary infection with *M. tuberculosis* has the following three elements: the primary parenchymal focus, intraparenchymal lymphangitis, and regional lymphadenitis (Figs. 18.2 and 18.3). At least 70% of primary pulmonary foci are subpleural, with spread through lymphatics to the regional lymph nodes. After several weeks, hypersensitivity develops, with regional node enlargement and the potential for caseating necrosis. Caseating lesions have a high density of actively multiplying bacilli, which spread rapidly to adjacent lymphatics. The hallmark of early tuberculosis is excessive unilateral mediastinal lymphadenitis compared with the relatively insignificant focus in the lung. Hilar adenopathy is unilateral in 80% or more of cases of tuberculosis.

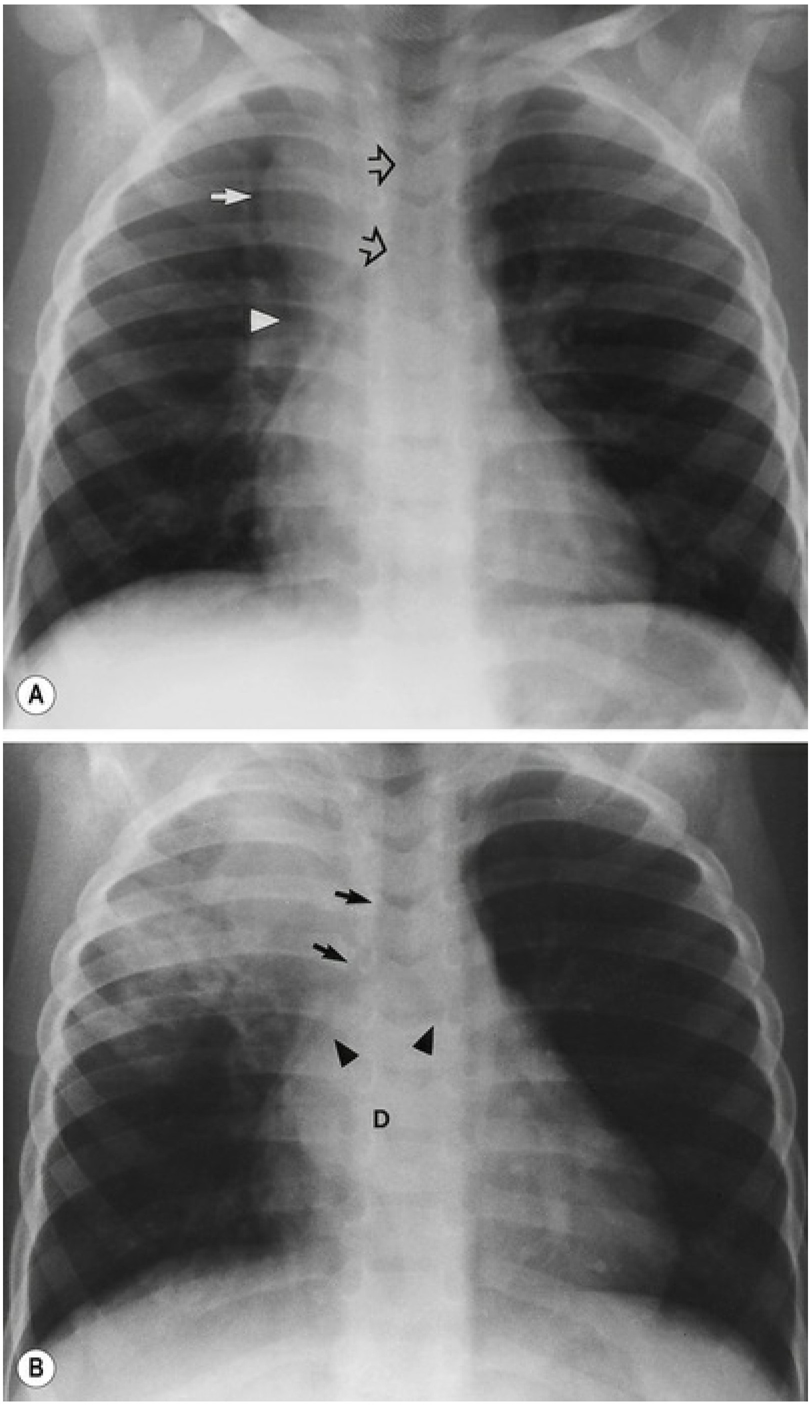

FIGURE 18.2 (A) Chest radiograph of a child with tuberculosis shows right paratracheal adenopathy (*closed arrow*) and right tracheobronchial adenopathy (*arrowhead*), causing effacement of the right lateral aspect of trachea (*open arrows*). (B) Chest radiograph of the same patient 4 months later (without therapy) shows right upper lobe pneumonia with subtle effacement of the right lateral aspect of the trachea and right mainstem bronchus, indicating right hilar and right paratracheal adenopathy (*arrows*). There is splaying of the carina (*arrowheads*) and double density

(*D*) of the lower mediastinum centrally, indicating subcarinal adenopathy.

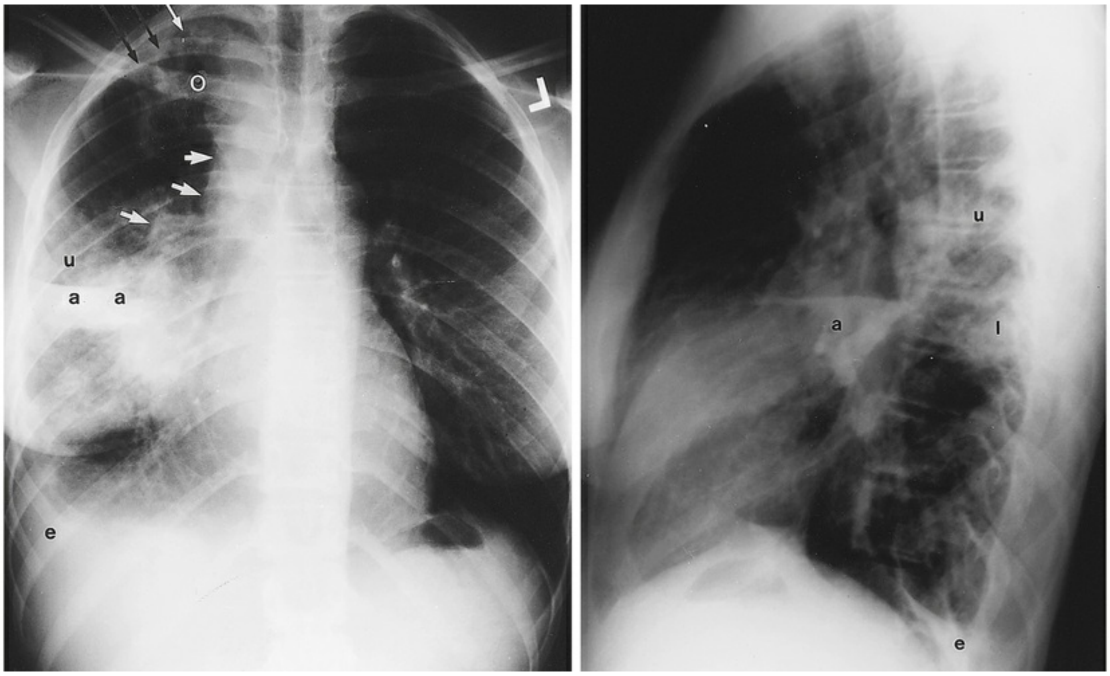

FIGURE 18.3 Chest radiographs of a child with reactivated tuberculosis show cystic changes in the apex of the right upper lobe (*open circle*) and pleural thickening in the superior hemithorax (*long arrows*). There is a right pleural effusion (e); right paratracheal, tracheobronchial, and hilar adenopathy (*short arrows*); and atelectasis or pneumonia in the right middle lobe (a), right upper lobe (u), and right lower lobe (l).

Infection can spread beyond the hilar and tracheobronchial nodes to the more distant right upper paratracheal nodes (the ones most often affected) and deep cervical (supraclavicular) nodes.[5] Additionally, apical subpleural primary infections can drain directly to the supraclavicular nodes. In one series of patients, 14 of 54 patients with a primary lesion in the right upper lobe had ipsilateral enlargement of deep cervical nodes.[6]

Enlargement of hilar nodes adjacent to bronchi can cause bronchial obstruction with the collapse or consolidation or fan-shaped segmental lesion typical of childhood tuberculosis. Infection and inflammation of the bronchial wall can occur, and obstruction of the lumen rarely can result in sudden death or in obstructive hyperaeration, segmental atelectasis, or secondary pneumonia. Multiple segmental lesions can occur, usually in the same lung.

Calcification follows caseous necrosis and occurs more often in children and in the regional lymph nodes than in the primary pulmonary focus. Extensive calcification is uncommon with early treatment, which prevents caseation.

In one series of CT performed in 23 young adults presenting with tuberculous mediastinal or hilar lymphadenitis, pulmonary involvement was demonstrated in 14 patients.[7] There was remarkable preponderance of involvement of the right paratracheal and tracheobronchial nodes. Nodes larger than 20 mm in diameter invariably showed central areas of relatively low density and peripheral rim enhancement that was irregular in thickness.

Nontuberculous Mycobacteria.

In immunocompromised children (and occasionally in healthy young children), nontuberculous mycobacteria can cause (1) extensive hilar and paratracheal lymphadenopathy with or without parenchymal disease and (2) endobronchial disease with atelectasis.[8] In all reported patients in one series, the organism was isolated from lymph node, lung, or bronchoalveolar lavage. Lymphadenopathy can be unilateral or bilateral, and nodes undergo extensive caseating necrosis.

Mycoplasma pneumoniae.

Radiographic findings in 56 patients with pneumonia (21 younger than 20 years) due to *M. pneumoniae* revealed that 22% of patients had hilar or paratracheal node enlargement, and 14% had pleural effusion.[9,10]

Bartonella henselae.

A few patients with cat-scratch disease have been described with mediastinal and peripheral lymphadenopathy. Mediastinal node biopsy in one patient revealed granuloma with microabscesses.[11]

Yersinia enterocolitica.

Significant bilateral self-limited hilar adenopathy without pneumonia due to *Y. enterocolitica* has been described in several adults. All patients recovered without therapy. The diagnosis was based on results of culture or serum agglutination titers.[12]

Lung Abscess.

Lung abscess frequently is associated with anaerobic infections but can occur in the course of any necrotizing pneumonia. Mediastinal lymphadenopathy is not unusual.

Bronchiectasis.

In children and adults, bronchiectasis of any etiology (e.g., associated with congenital anomaly, foreign body), and especially that associated with cystic fibrosis in children, can cause mediastinal lymphadenopathy. In one study of CT in patients with bronchiectasis, mediastinal lymphadenopathy (nodes >10 mm in diameter) was present in 29% of patients.[13]

Fungal Causes

Histoplasma capsulatum.

Infection due to *Histoplasma capsulatum* can take multiple clinical forms (Figs. 18.4 and 18.5). In the immunocompetent host, histoplasmosis most frequently is subclinical, recognized incidentally. In symptomatic infection, cough or chest pain is most common. Mediastinal lymphadenopathy, an uncommon finding in disseminated infection, is the most common manifestation in healthy children with self-limited infection. Of 35 children hospitalized with histoplasmosis between 1968 and 1988, 29 (83%) had pulmonary infection, mediastinal infection, or both. Chest radiograph was abnormal in 31 (91%), revealing adenopathy in 25 (74%) and infiltrates in 19 (56%).[14] Isolated mediastinal adenopathy can be difficult to distinguish from lymphoma.[15,16] Rarely, massive inhalation of fungus causes disseminated, symptomatic primary infection with fever, cough, and massively enlarged mediastinal lymph nodes. The differentiation is important because histoplasmosis is mild and self-limited in most immunocompetent people. Antifungal therapy is used in those with acute diffuse pulmonary infection, chronic pulmonary infection, progressive disseminated disease, and mediastinal adenitis associated with obstructive symptoms.

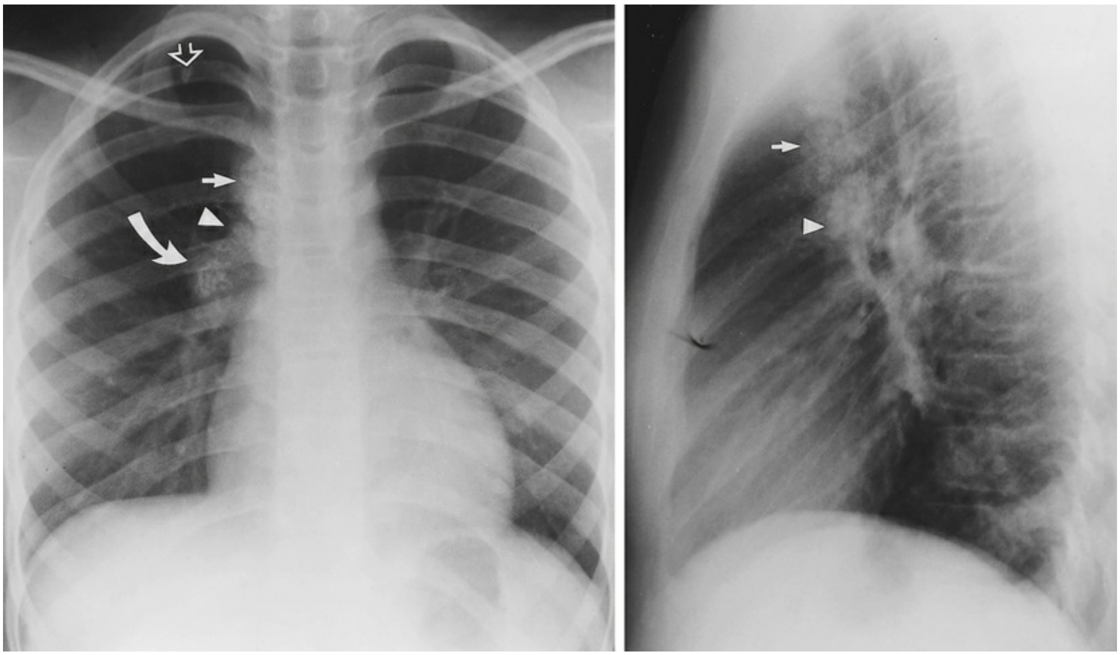

FIGURE 18.4 Chest radiographs of a child with healed histoplasmosis shows granuloma in right upper lobe (*open arrow*), calcified paratracheal nodes (*straight arrow*), tracheobronchial nodes (*arrowhead*), and calcified right hilar nodes (*curved arrow*).

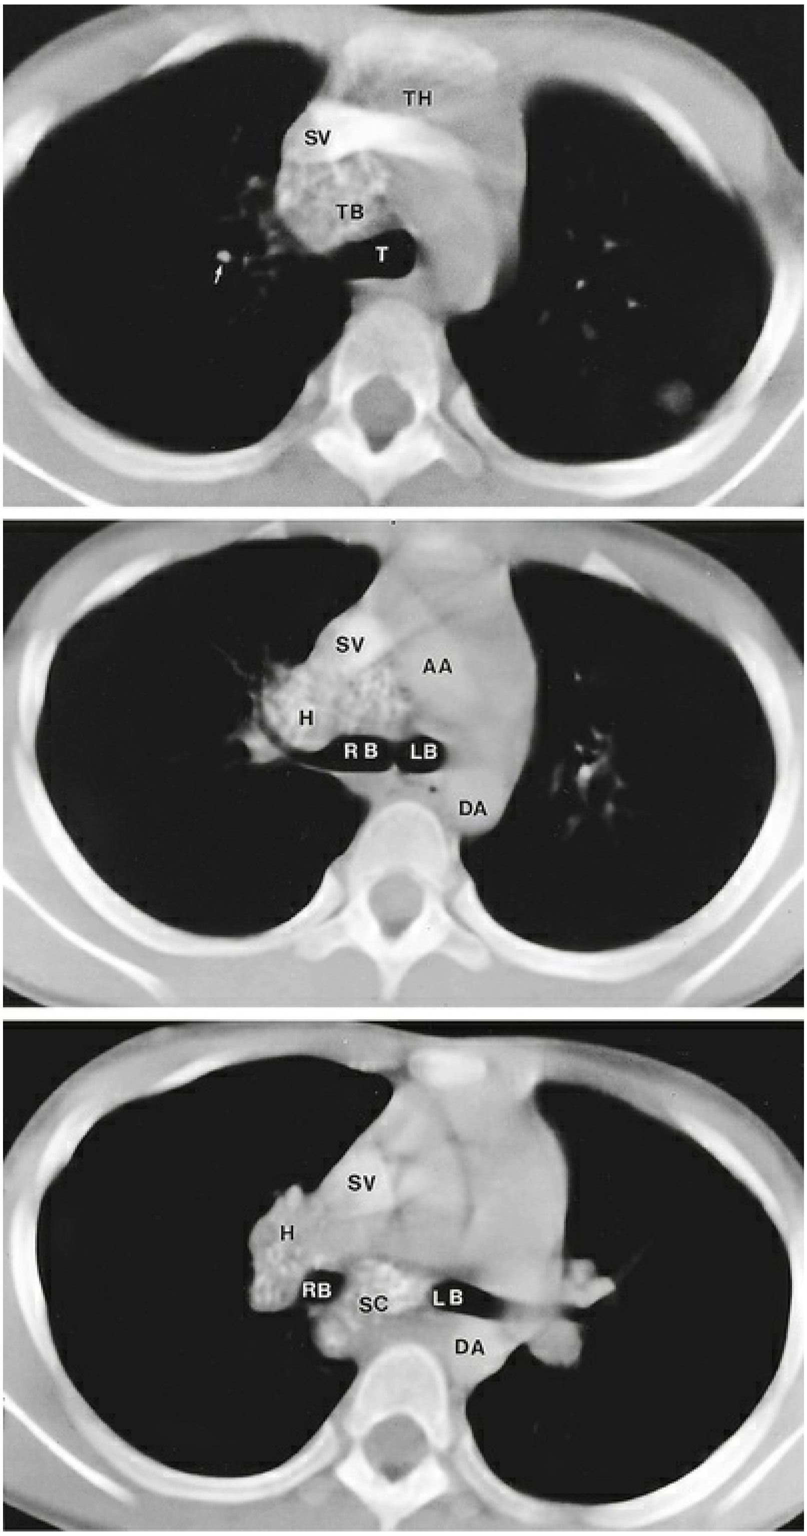

FIGURE 18.5 Enhanced computed tomography scan of the patient in Fig. 18.4 shows extensive right tracheobronchial, right hilar, and subcarinal lymphadenopathy. Particulate calcification within the nodes is characteristic of healed histoplasmosis. *Arrow* indicates calcified granuloma in right upper lobe. AA, ascending aorta; DA, descending aorta; H, calcified right hilar node; LB, left mainstem bronchus; RB, right

mainstem bronchus; SC, calcified subcarinal nodes; SV, superior vena cava; T, trachea; TB, calcified tracheobronchial nodes; TH, thymus.

In the otherwise healthy host, marked enlargement of mediastinal lymph nodes can cause obstruction of bronchi, the superior vena cava, or the esophagus. Additionally, a group of large nodes can become necrotic and matted to form a large single mediastinal mass known as an acute mediastinal granuloma. Most such masses resolve spontaneously; the effect of antifungal therapy has not been studied.

In the populations with deficiencies in cellular immunity, pulmonary histoplasmosis can be a difficult diagnosis, mainly because it is not often considered. Histoplasmosis generally occurs sporadically, manifesting as a prolonged febrile illness with subacute pulmonary symptoms.[17] Disseminated histoplasmosis, both in transplant recipients and in patients with an underlying condition treated with anti−tumor necrosis factor-α therapy, is well described. Symptoms frequently are nonspecific, and signs of respiratory infection may be absent. Diagnosis in this setting requires detection of *Histoplasma* antigen in the serum and urine.[18] Disseminated disease once noted frequently in people living in endemic areas with advanced human immunodeficiency virus (HIV) infection is rarely seen now owing to the early diagnosis and treatment of HIV infection.

Coccidioidomycosis immitis.

Coccidioidomycosis occurs primarily in the southwestern United States. It is subclinical in children in 60% of cases. An insignificant flu-like illness or severe respiratory infection with lobar pneumonia and pleural effusions can occur. Radiographic findings are nonspecific; bronchopneumonic infiltrates often are associated with enlargement of hilar nodes. Cavitation, nodule formation, or calcification occurs in a minority of patients.

Parenchymal infiltrates commonly are associated with hilar lymphadenopathy. More extensive mediastinal adenopathy is not considered part of the primary complex and may represent dissemination. Rarely, bilateral hilar adenopathy occurs without apparent pulmonary disease.

Paracoccidioides brasiliensis.

A progressive chronic disease due to *P. brasiliensis,* paracoccidioidomycosis preferentially involves the lungs and reticuloendothelial system. It occurs predominantly in a few Latin American countries. Only about 2% of cases occur in children. Pulmonary lesions can be infiltrative, fibrotic, fibrocaseous, or cavitary. Enlargement of hilar and mediastinal lymph nodes is observed. Enlargement of liver, spleen, and other lymph nodes (e.g., cervical, inguinal, and mesenteric) also occurs. Complications include suppuration and fistula formation and scarring of affected nodes with residual pulmonary fibrosis.

Pneumocystis jirovecii.

A patient with acquired immunodeficiency syndrome and *P. jirovecii* pneumonia with calcified hilar and mediastinal nodes has been reported.[19]

Other.

An immunocompetent child with fever, pneumonia, and a posterior mediastinal mass with hilar and subcarinal lymphadenopathy was originally thought to have lymphoma, but at biopsy, a granuloma with broad septated fungal hyphae with right-angle branching compatible with zygomycosis was found.[20]

Viral Causes

Epstein-Barr Virus.

Generalized lymphadenopathy secondary to extensive lymphocytic hyperplasia can include the mediastinum.[21,22] In transplant recipients undergoing immunosuppression, manifestations of lymphoproliferative disease related to Epstein-Barr virus can include generalized or localized adenopathy, including involvement of the mediastinal nodes.

Rubeola.

Pulmonary infiltrates and hilar adenopathy appearing early in the course of measles are well described. In one series of 130 children with measles, 55% had pulmonary infiltrates and 74% had hilar adenopathy.[23]

Noninfectious Causes

Malignancy

Lymphomas (Figs. 18.6 and 18.7) characteristically occur in the anterior and middle mediastinum and are the third most common cause of mediastinal masses in children. The most common manifestation of Hodgkin lymphoma or non-Hodgkin lymphoma is painless lymph node enlargement, most often in the cervical or supraclavicular chains. Of patients with Hodgkin lymphoma, 50% to 60% have mediastinal lymphadenopathy (usually bilateral) and evidence of tracheobronchial compression at the time of diagnosis. Involved nodes are hilar (≥25%), subcarinal (22%), posterior mediastinal (5%), and cardiophrenic angle (8%). Ipsilateral pulmonary parenchymal involvement is present in 10% of patients.

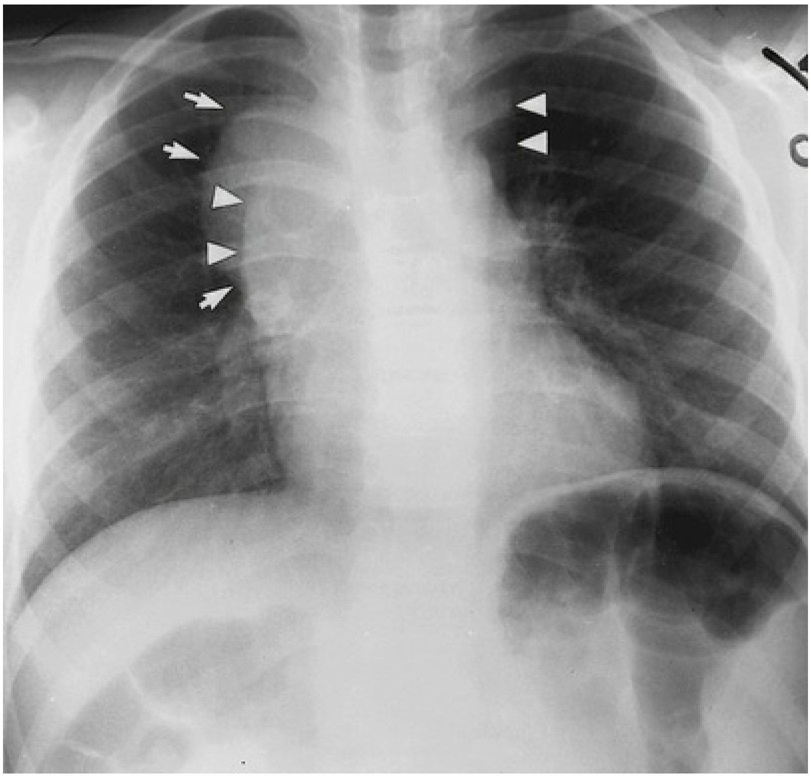

FIGURE 18.6 Chest radiograph of a child with mixed-cell Hodgkin disease shows right paratracheal (*arrows*) and tracheobronchial lymphadenopathy (*arrows*). The superior mediastinum is widened on the left as well,

indicating enlargement of anterior mediastinal nodes (*arrowheads*).

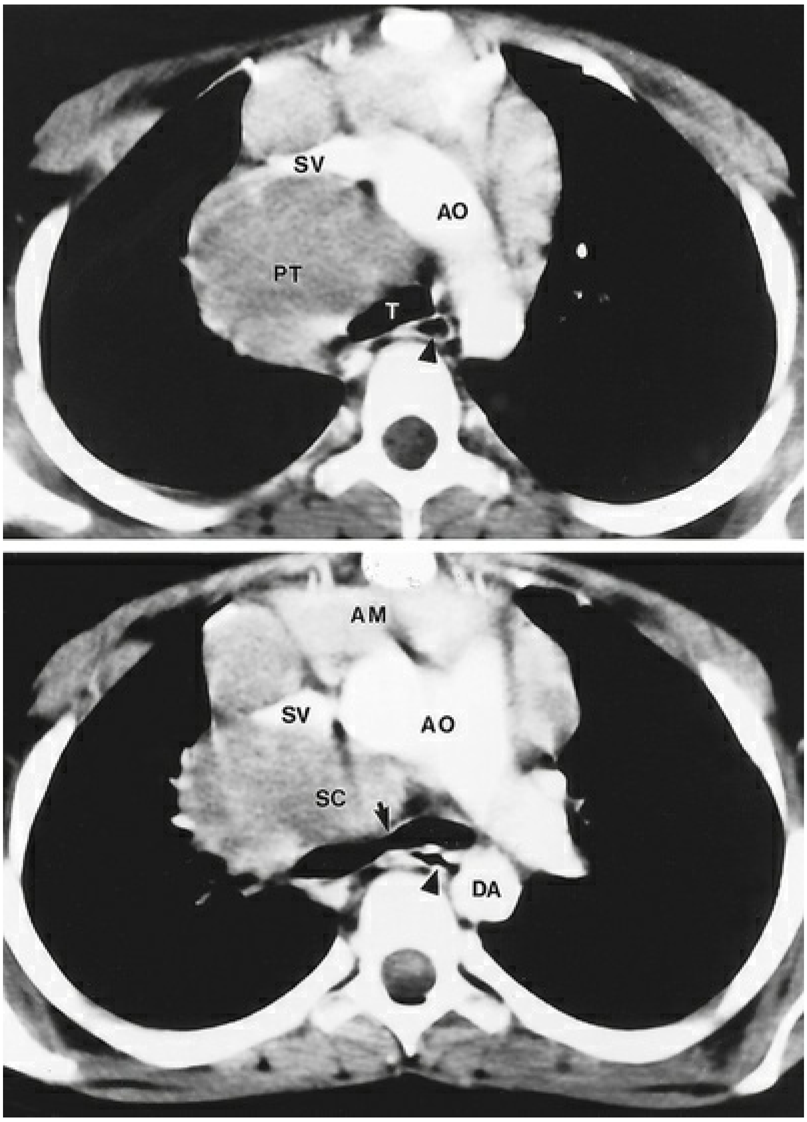

FIGURE 18.7 Enhanced computed tomography scans of a child with mixed-cell Hodgkin disease show extensive mediastinal adenopathy. *Arrow* indicates carina, and *arrowhead* indicates esophagus containing air. AM, anterior mediastinal nodes; AO, aortic arch; DA, descending aorta; SC, subcarinal nodes; SV, superior vena cava; T, trachea.

Childhood non-Hodgkin lymphoma is a rapidly proliferating malignancy, usually affecting adolescent males and often with a duration of symptoms of only 4 to 6 weeks. Lymphoblastic lymphoma and the closely related acute lymphoblastic leukemia often manifest indistinguishably, with mediastinal adenopathy and compression. Dissemination is present in 70% of children at the time of diagnosis. Non-Hodgkin lymphoma can arise in any lymphoid tissue and in numerous extralymphatic sites. Painless, rapidly progressive enlargement of cervical, supraclavicular, and axillary nodes is a common presenting complaint. With involvement of these nodes, an anterior mediastinal tumor is common (50% to 70%), as are pleural effusions.

Other Causes

Sarcoidosis.

Sarcoidosis is a multisystem granulomatous disease of unknown cause that is relatively uncommon in children. The incidence appears to become more significant beginning at about 13 years of age.[24] Sarcoidosis most commonly involves the lungs, lymph nodes, eyes, skin, liver, and spleen. Nonspecific symptoms consist of fever, weight loss, cough, fatigue, lethargy, lymphadenitis, visual disturbances, and rashes. In large series of children and adults, 90% of patients have bilateral involvement of the lungs and hilar lymph nodes.[25,26] In children, bilateral hilar lymphadenopathy, occasionally involving the paratracheal nodes, was associated with parenchymal involvement in 50% of cases.[26] Patients should be evaluated for ocular involvement as well as other visceral sites of disease.

Giant Lymph Node Hyperplasia (Castleman Disease).

Castleman disease, a rare disease in children younger than 14 years, can manifest as an asymptomatic mass in the mediastinum or neck, along the aorta or in the abdomen.[27,28] Some patients have prolonged fever, anemia, weight loss, splenomegaly, hypergammaglobulinemia, elevated erythrocyte sedimentation rate (ESR), bone marrow plasmacytosis, and a poor outcome. Microscopically, the large, well-circumscribed ovoid nodes 3 to 8 cm long are characterized by lymphoid follicular hyperplasia with and without germinal center formation and marked capillary proliferation with endothelial hyperplasia. Human herpesvirus 8 has been found in the nodes of affected patients. Surgical removal of localized nodes for diagnosis and therapy may relieve systemic symptoms. Recurrences have not been reported in children. Pilot study data suggest that valganciclovir-zidovudine combination therapy was effective in HIV-infected adults taking highly active antiretroviral therapy.[29]

Wegener Granulomatosis.

Mediastinal adenopathy with tracheal and bronchial stenosis associated with Wegener granulomatosis has been reported rarely in children. In these cases, disease was limited to the airways and sinuses.

Chronic Granulomatous Disease.

Hilar adenopathy in association with pneumonia raises suspicion of chronic infection or granuloma formation. Patients with chronic granulomatous disease frequently have mediastinal adenopathy in conjunction with pneumonia.

Graves Disease.

Thymic enlargement simulating an anterior mediastinal mass has been noted in adults and adolescents with Graves disease. In such cases, thyrotropin receptor autoantibodies stimulate the thyroid and some extrathyroid tissues including the thymus. Clinical findings of hyperthyroidism may be subtle but measurement of thyroid hormone levels are diagnostic.[30]

Diagnostic Approach

The diagnostic approach depends on the age of the patient, exposures, presence and progression of symptoms, associated physical findings, and specific abnormalities of imaging studies (see Table 18.4). Results of serologic tests (e.g., for *Bartonella, Mycoplasma, Histoplasma* infection) and the tuberculin skin test may confirm the diagnosis, averting the need for tissue biopsy. *H. capsulatum* antigen detection is most sensitive for disseminated disease but can be negative in pulmonary histoplasmosis. *Histoplasma* antigen found in serum, urine, or bronchoalveolar lavage fluid, however, can confirm the diagnosis if all symptoms and signs are compatible. Rapidly enlarging masses, in the absence of a confirmed, compatible diagnosis, require prompt biopsy. Optimal therapy depends on rapid and accurate diagnosis.[31,32]

Subacute infections associated with hilar lymphadenopathy can be difficult to distinguish from lymphoreticular malignancy. In one study of 37 children with anterior and middle mediastinal masses, 16 had lymphomas and 21 had histoplasmosis.[33] The two entities could not be distinguished on the basis of patient age or sex, fever, weight loss, duration of illness, anemia, ESR, or lung infiltrates and calcifications. Anterior mediastinal masses were due to lymphoma in 81% of cases and histoplasmosis in 5%. Of the patients with lymphomas, only 7% had *Histoplasma* complement fixation titers of 1 : 8 or higher, but 67% of patients with histoplasmosis had titers of 1 : 32 or higher. The authors of this study concluded that biopsy of anterior mediastinal masses should be performed. Immunodiffusion testing for *H. capsulatum,* however, is highly specific. The finding of H bands is highly suggestive of acute infection (see Chapter 250).

Abdominal and Retroperitoneal Lymphadenopathy

Angela L. Myers

Lymphadenopathy, the abnormal enlargement of lymph nodes, can result from a wide variety of infectious and noninfectious causes. Acute enlargement of superficial lymph nodes caused by infection can occur over a period of days, accompanied by pain and tenderness to palpation, resulting in lymphadenitis. Alternatively, the enlargement of nodes can occur over weeks to months, with little tenderness, representing a more chronic inflammatory process. Abdominal and retroperitoneal lymphadenopathy is a diagnosis made by imaging techniques such as ultrasonography (US), computed tomography (CT), or magnetic resonance imaging (MRI). Without sequential imaging studies, it can be unclear whether enlargement represents a new, rapidly evolving process or a more prolonged, chronic, relatively stable one. Without the ability to examine the lymph nodes directly, the clinician must rely on clues from the history and physical examination to formulate a diagnosis.

Inflammation in lymph nodes may be the direct result of infection in the tissues (or other lymph nodes) that the nodes drain or a consequence of dissemination of an organism through the bloodstream. Tissues and organs of the abdomen and retroperitoneal space can be infected by a variety of pathogens and through various routes (see Chapters 66 and 67).

Epidemiology and Differential Diagnosis

Abdominal and retroperitoneal lymphadenopathy in children can have infectious and noninfectious causes. Malignant processes and serious infection are the primary concerns; although incidental lymphadenopathy also is found in asymptomatic children.[1-8] A systematic approach to evaluation for infection requires consideration of selected factors from the history and clinical examination (Box 19.1).

Box 19.1

Evaluation of Patients With Lymphadenopathy of Suspected Infectious Etiology

Symptoms

Duration of symptoms: acute (days) or chronic (weeks to months)

Presence of weight loss, fever, night sweats

Presence of organ system–specific symptoms: diarrhea, abdominal pain, jaundice, dysuria, flank pain, hip pain, back pain

Exposures

Exposure to animal bites or scratches: cats, rodents, farm animals, ticks

Travel to areas endemic for enteric bacteria, parasites, or fungal pathogens: *Histoplasma, Coccidioides, Mycobacterium*, or *Plasmodium* spp.

Ingestion of unpasteurized dairy products

Risk factors for HIV infection

Underlying Disorders

Concomitant infection elsewhere in the patient

History of previous or chronic infection of liver or gallbladder, spleen, pancreas, bowel, kidney or ureters, bladder, ovaries or uterus, iliopsoas muscle, or vertebral bodies

Presence of underlying immunocompromising disorders: malignant tumors, chemotherapy, corticosteroid therapy, HIV infection

Congenital immunodeficiencies: chronic granulomatous disease, severe combined immunodeficiency

Transplantation: immunodeficiency and posttransplantation lymphoproliferative disorders

Crohn disease

Celiac disease

Gaucher disease[64]

Physical Examination

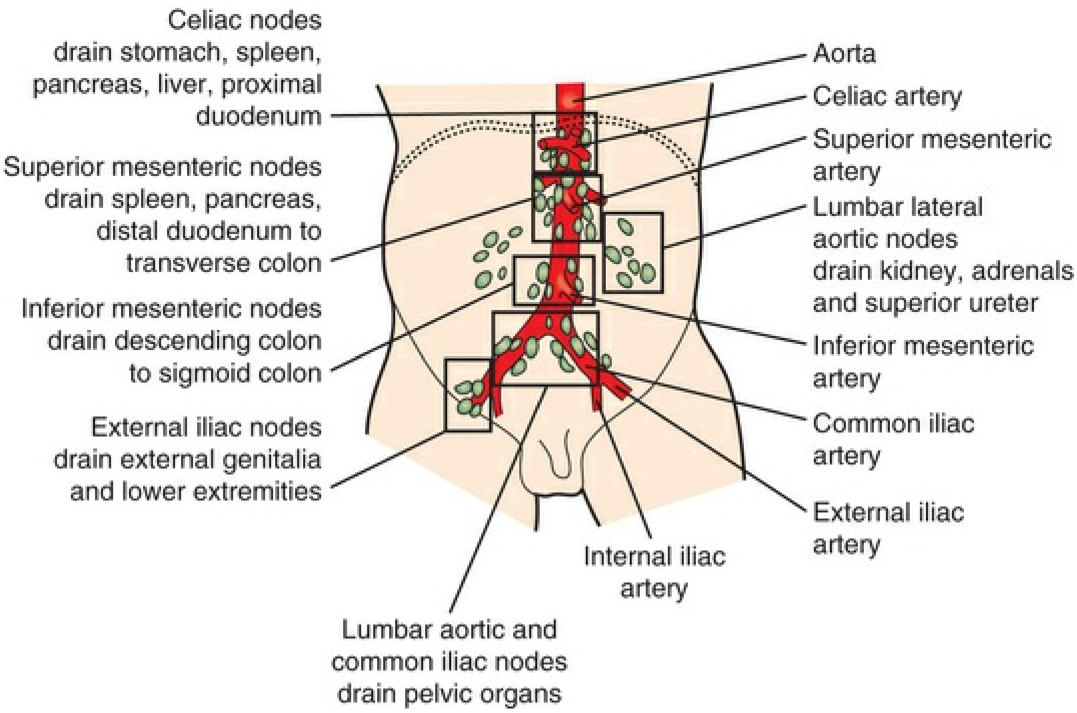
Lymphadenopathy: focal versus regional or systemic

Evidence of infection in tissues or organs drained by lymph nodes

Evidence of systemic infection: Epstein-Barr virus infection, cat-scratch disease, tuberculosis, *Yersinia* spp., salmonellosis

HIV, human immunodeficiency virus.

Regional lymph nodes that drain the organs and tissues from the abdomen, retroperitoneal space, and lower extremities are shown in Fig. 19.1.[4,9] Focal, deep lymphadenopathy suggests infection in the adjacent draining structures or lymph node groups; generalized adenopathy suggests a disseminated process that is likely to involve other lymph nodes, superficial ones that may be palpably enlarged, as well as the liver and spleen.



Celiac nodes drain stomach, spleen, pancreas, liver, proximal duodenum
Superior mesenteric nodes drain spleen, pancreas, distal duodenum to transverse colon
Inferior mesenteric nodes drain descending colon to sigmoid colon
External iliac nodes drain external genitalia and lower extremities
Aorta
Celiac artery
Superior mesenteric artery
Lumbar lateral aortic nodes drain kidney, adrenals and superior ureter
Inferior mesenteric artery
Common iliac artery
External iliac artery
Internal iliac artery
Lumbar aortic and common iliac nodes drain pelvic organs

FIGURE 19.1 Location and drainage patterns of deep abdominal lymph nodes.

Infectious causes of enlarged superior or inferior mesenteric lymph nodes include most of the bacterial, viral, and parasitic pathogens that cause gastroenteritis. Mesenteric lymph node enlargement in association with an acute, symptomatic febrile illness that most often manifests as abdominal pain is referred to as *mesenteric lymphadenitis*. *Yersinia, Salmonella,* and *Shigella* spp., *Escherichia coli,* adenoviruses, enteroviruses, and *Entamoeba histolytica* are important causes of mesenteric lymphadenitis, and each has a characteristic constellation of clinical and laboratory findings (see Chapter 66).[4,9-16] Associated inflammation of the terminal ileum and ileocecal junction suggests infectious causes, such as *Yersinia,*[11,17] *Mycobacterium tuberculosis* or *M. bovis,* as well as Crohn disease.[13,18,19] *M. tuberculosis* is considered especially if the child was born in an endemic region, has traveled to tuberculosis-endemic areas, or may have ingested contaminated food products (e.g., homemade unpasteurized cheese).[18,20-22]

Epstein-Barr virus (EBV) and *Bartonella henselae* infection are the most commonly reported infectious causes of abdominal lymphadenopathy in otherwise healthy children. In mononucleosis, the accompanying malaise, pharyngitis, systemic lymphadenopathy, and hepatosplenomegaly often lead to the diagnosis.[23] Peripheral findings of a papule at the site of inoculation and of regional peripheral lymphadenopathy frequently are present in patients with cat-scratch disease. However, fever, with or without abdominal pain, in the absence of peripheral findings, can be the presentation of *B. henselae* infection in the liver, spleen, or abdominal lymph nodes.[24-27] Other less common systemic infections include malaria, toxoplasmosis, and pentastomiasis.[28-31]

Tuberculosis in children can manifest with abdominal lymphadenopathy as the sole anatomic manifestation of systemic infection. Lymphadenopathy can occur during primary infection or during reactivation of a previous infection. Both *M. tuberculosis* and *M. bovis* can cause symptomatic infection of the intestines, lymph nodes, peritoneum, omentum, liver, or spleen.[20-23,32,33] Additionally, a recently recognized mycobacterium species, *M. gastri,* has been reported to cause disseminated infection with extensive abdominal lymphadenopathy.[34] Children can have symptoms of weight loss, fatigue, and intermittent abdominal pain in the absence of abdominal physical findings. The clinical presentation can mimic inflammatory bowel disease.[35] Because low numbers of organisms typically are present, polymerase chain reaction (PCR) of biopsy specimen is a more reliable test than mycobacterial stain or culture. If the infection is caused by *M. tuberculosis,* hilar adenopathy also may be detected on chest radiograph, but, in most cases, abdominal tuberculosis occurs in the absence of pulmonary disease.

Lymphoproliferative syndromes caused by EBV and characterized by abdominal lymphadenopathy have been well described.[24,36-38] At one center, approximately 8% of pediatric transplant recipients developed lymphoproliferative syndrome.[36] Approximately one half of children with an EBV-related abdominal lymphoproliferative disorder have abdominal pain; one fourth have enlarged liver or spleen or manifest an abdominal mass. Evidence of EBV infection of B lymphocytes usually is present.

In children with symptomatic human immunodeficiency virus (HIV) infection, abdominal lymphadenopathy can signify the underlying HIV infection, an HIV-related cancer, or secondary infection.[2,39] In particular, *M. avium* complex (MAC) infection can cause massive systemic lymphadenopathy, including the mesenteric and retroperitoneal lymph nodes.[40] Congenital immunodeficiencies, such as chronic granulomatous disease, also rarely can be characterized by mesenteric lymphadenopathy.[41]

Mesenteric lymphadenopathy can accompany noninfectious inflammation of the bowel, such as that due to Crohn disease[14] or celiac disease.[42,43] Abdominal lymphadenopathy can be a systemic manifestation of a number of disorders of unknown cause, including sarcoidosis,[44] Castleman disease,[45] Rosai-Dorfman disease,[3] or familial Mediterranean fever.[46]

Diagnostic Tests

Imaging Studies

US has been used to assess the significance and degree of abdominal lymphadenopathy in both infectious and noninfectious conditions,[7,47,48] including cat-scratch disease[49] and abdominal tuberculosis.[50,51] Subtle differences detectable by US can help differentiate between infectious causes of enlarged nodes. In studies in which US and CT have been compared, CT is more sensitive for detecting abdominal lymphadenopathy,[50,52] aiding in the diagnosis of both abdominal and retroperitoneal lymphadenopathy.[14,20,53] MRI has been used to evaluate lymphadenopathy in both the abdominal and retroperitoneal spaces, has advantages over other imaging techniques for the detection of vascular lesions and tumors, and appears to be at least equivalent to CT in intra-abdominal infection.[22,54-56]

Clinical Findings and Laboratory Tests

Clues to the cause of lymphadenopathy are based on physical findings that can include systemic lymphadenopathy or hepatosplenomegaly. Other physical findings of infection of the respiratory tract, gastrointestinal tract, skin, skeletal system, cardiovascular system, or genitourinary system also can provide clues to the primary site of infection.

In the immunocompetent child, a tuberculin skin test (TST) remains one of the most sensitive and specific techniques for diagnosis of infections caused by *M. tuberculosis* or *M. bovis* in young children. However, shortages of purified protein derivative may hinder the use of TST.[57] Additionally, false-negative test results have been seen in conjunction with disseminated tuberculosis and immunocompromising conditions. Diagnostic assays based on production of interferon γ (IFNγ) by cultured peripheral blood lymphocytes after in vitro exposure to purified proteins from *M. tuberculosis* are useful in adults, but may not be reliable in children younger than 5 years.[58–60] For older children, IFNγ release assays may have equal or improved senstitivity compared with traditional TST, when used in the appropriate clinical setting.[61,62] Further, these tests can differentiate *M. tuberculosis* infection from *M. bovis*, bacille Calmette-Guérin, and most nontuberculous mycobacterial infections.

Biopsy

Many infections that lead to abdominal lymphadenopathy can be detected by specific serologic tests, including infections caused by *B. henselae,* EBV, cytomegalovirus, *Toxoplasma* spp., and HIV. The types of cultures obtained from blood, urine, stool, or biopsy specimens should be directed toward the suspected pathogens, noting the particular lymph node group affected, pertinent history and clinical findings, and associated or underlying diseases.

When tissue samples are required for accurate diagnosis, particularly in the case of tumors, the techniques discussed in Chapter 67 are useful for the diagnosis not only of organ disease but also of lymph node disease. Options include open surgical biopsy and laparoscopic biopsy or fine-needle biopsy, directed by US or CT. Considerations for choosing the optimal technique in individual cases include the volume of tissue required for diagnosis, the urgency for arriving at a diagnosis, institutional procedural experience, and the ancillary support services available. In general, histologic diagnosis of specific tumors requires larger amounts of tissue than are required for diagnosis of infection.

Special stains, cultures, and PCR assays can be used to identify bacteria, fungi, mycobacteria, or viruses. Biopsy samples are examined histologically for evidence of acute or chronic inflammation, abscess or granuloma formation, or primary or metastatic tumors. Pathogens generally produce characteristic histopathologic findings. For example, caseating granuloma characterizes tuberculosis, but stellate granuloma is more suggestive of infection due to *B. henselae.*

Therapy

Treatment of abdominal and retroperitoneal lymphadenopathy is dependent on the underlying etiology. Although many infectious causes are benign and self-limited, antimicrobial therapy can be beneficial depending on the pathogen implicated (e.g., *Salmonella Typhi*). Chapters that discuss specific pathogens should be reviewed. Treatment of abdominal lymphadenopathy caused by posttransplantation lymphoproliferative disorder ranges from reduction of immune suppression alone to courses of chemotherapy in those with malignant transformation.[37] Immune modulators are the primary modality of treatment in patients with inflammatory bowel disease who are unresponsive to conventional therapies.[63]

Localized Lymphadenitis, Lymphadenopathy, and Lymphangitis

Angela L. Myers

Lymphadenopathy and Lymphadenitis

Lymphadenopathy is defined as disease of the lymph nodes, but the term is more commonly used to denote lymph node enlargement. Enlarged lymph nodes can arise in association with a wide variety of infectious, inflammatory, or neoplastic disease processes. *Lymphadenitis* refers to a localized inflammatory process, usually bacterial, within a lymph node or group of nodes. Lymphadenitis can develop acutely or chronically and can be pyogenic or granulomatous in nature.

Other chapters in this textbook are devoted to the evaluation and management of generalized lymphadenopathy (see Chapter 16) and lymphadenopathy of the cervical nodes (see Chapter 17), hilar nodes (see Chapter 18), inguinal nodes (see Chapter 50), and abdominal nodes (see Chapter 19). This chapter focuses on regional lymph node disease encountered in the remaining superficial locations.

Pathogenesis

Enlarged lymph nodes can result from intrinsic proliferation of lymphocytes or reticuloendothelial cells or from infiltration by cells from an extrinsic source. Lymphocytes or lymphoblasts proliferate in response to antigenic stimuli, producing lymph node enlargement, which recedes after antigen clearance. Pathogens that are able to survive intracellularly can provide persistent stimuli and can be associated with chronic lymphatic cellular hyperplasia. Extrinsic invasion of lymph nodes occurs by neutrophils in response to bacteria and bacterial toxins, by histiocytes in histiocytosis and certain storage diseases, and by malignant cells in leukemia, lymphoma, and metastatic solid tumors.

Etiologic Agents

The pyogenic bacteria *Staphylococcus aureus* and *Streptococcus pyogenes* account for more than 80% of acute bacterial lymphadenitis.[1] Lymph node infection usually can be attributed to spread from an adjacent skin infection or inoculation site; occasionally, no clear origin is evident. Acute localized lymphadenitis with or without overlying cellulitis can develop in an infant as a manifestation of late-onset bacteremic group B streptococcal disease.[2,3] Subacute development of localized lymph node enlargement in healthy children occurs with cat-scratch disease (i.e., *Bartonella henselae* infection) and with nontuberculous mycobacterial infection. Adenitis with fungal pathogens such as *Aspergillus* or *Candida* can occur in immunosuppressed patients, including those with primary immune deficiency (e.g., chronic granulomatous disease) and those who are undergoing chemotherapy for an oncologic diagnosis.[4–6] Unusual pathogens can produce lymphadenitis in otherwise healthy people after specific environmental exposures (e.g., *Francisella tularensis* after a tick bite or animal skinning, *Corynebacterium pseudotuberculosis* in sheep handlers).

History and Clinical Findings

Certain clinical features may be useful in guiding the evaluation of localized lymph node infections (Table 20.1). Small inguinal, cervical, or axillary lymph nodes can be palpated in about one third of healthy infants.[7] Subsequent antigenic stimulation leads to steady enlargement of lymphoid tissue from infancy through puberty, and most healthy children have palpable cervical, inguinal, and axillary nodes.[8] In contrast, other peripheral node groups (e.g., posterior auricular, supraclavicular, epitrochlear, iliac, popliteal), if palpable, are always considered abnormal.[9]

TABLE 20.1

Infections Associated With Localized Lymphadenopathy

Lymph Node Group	Area of Drainage	Palpable Nodes	Infectious Causes	
			Common	Less Common
Occipital	Back of scalp and neck	5% of healthy children	Impetigo Pediculosis (head lice) Tinea capitis Seborrheic dermatitis	Rubella Toxoplasmosis
Preauricular	Lateral portion of eyelids Lateral conjunctivae Skin above cheek, temple	Only with disease	Adenoviral conjunctivitis Parinaud syndrome due to cat-scratch disease	*Chlamydia* conjunctivitis Parinaud syndrome due to tularemia or herpes simplex virus infection
Axillary	Hand and arm	70%–90% of healthy children	Local pyogenic infection	Calmette-Guérin bacillus vaccine, fever, tuberculosis (scrofuloderma), hidradenitis suppurativa
	Chest wall, breast Upper lateral abdominal wall	—	Cat-scratch disease	—
Epitrochlear	Ulnar aspect of hand and forearm	Only with disease	Local pyogenic infection	Tularemia, cat-scratch disease, secondary or congenital syphilis
Iliac	Lower abdominal viscera Urinary and genital tract Lower extremities	Only with disease	Abdominal infection such as appendicitis, abdominal trauma, urinary tract infection	Pyogenic infection of lower extremity
Popliteal	Skin of	Only	Severe local pyogenic	—

	lateral foot and lower leg, knee joint	with disease	infection	

A careful history must be obtained regarding the time of onset and rate of lymph node enlargement (Box 20.1). The skin and soft tissue areas drained by the enlarged nodes are examined for signs of infection and disruption. History of exposure to animals is detailed. Occurrence of bites (including tick bites) or traumatic scratches or other papular or ulcerative skin lesions is elicited. Weight loss, protracted fever, rash, generalized lymphadenopathy, and hepatosplenomegaly suggests a systemic disease.[10]

Box 20.1

Clinical Clues to the Cause of Lymphadenopathy

History

Associated symptoms and duration of illness

Ingestion of unpasteurized milk or undercooked meat

Dental problems

Skin lesions or trauma with or without foreign body exposure

Animal exposures; flea or tick bites

Contact with tuberculosis

Drug usage (especially phenytoin)

Physical Examination

Dental disease

Ocular, otic, or oropharyngeal lesions

Skin lesions

Noncervical adenopathy

Hepatomegaly or splenomegaly

Lymph nodes associated with viral infection tend to be small, bilateral, freely mobile, and variably tender.[11] Erythema, warmth, and tenderness overlying a node typically indicate a pyogenic acute inflammatory response related to a bacterial pathogen. Fluctuation of the lymph node suggests acute pyogenic bacterial adenitis but also can be seen with more indolent pathogens, including nontuberculous mycobacteria (NTM), and an overlying violaceous hue raises suspicion of NTM (Fig. 20.1). Most acutely infected lymph nodes in children have a rubbery or firm consistency and are freely mobile. Fixation of nodes to underlying tissue or matting to each other can occur with bacterial adenitis but raises concern about a neoplastic process. Absence of fixation does not exclude malignancy, especially not lymphoma.

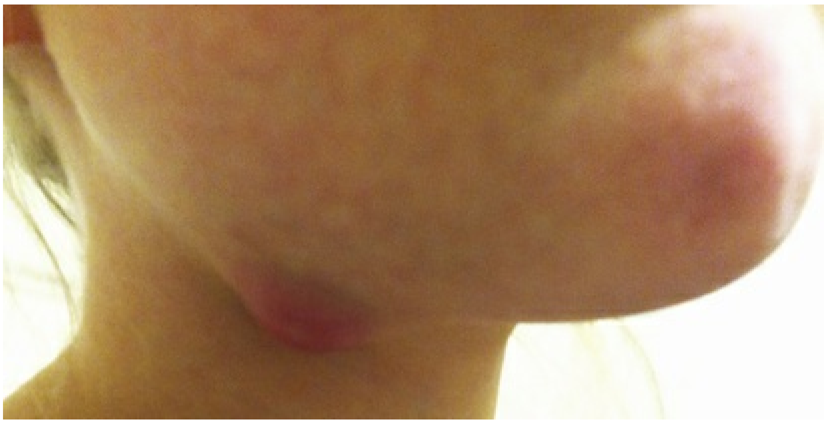

FIGURE 20.1 A 6-year-old girl has a violaceous submandibular lymph node consistent with nontuberculous mycobacterial infection. The lymph node was resected, and necrotizing granulomas with rare acid-fast bacteria were found on pathology review. (Courtesy of J. Christopher Day, MD, Children's Mercy Hospital, Kansas City, Missouri.)

Differential Diagnosis

Knowledge of lymphatic drainage patterns is essential for identification of the primary focus of infection and the most likely etiologic agents in the child with localized lymphadenopathy. The regions drained by specific lymph node groups are listed in Table 20.1, along with the associated infections encountered.

Occipital Nodes

The occipital lymph nodes drain the posterior scalp and can become enlarged by diseases such as impetigo, pediculosis capitis, tinea capitis, and inflamed seborrheic dermatitis. Tularemia often involves occipital nodes because a common site for tick bite in children is on the parieto-occipital scalp. Occurrence of the tick bite itself may be unknown or forgotten; it may have occurred a week or more earlier. A history of exposure to a tick-infested area should raise suspicion. The scalp should be inspected carefully for a papule or an ulcer because ulceroglandular tularemia is more common than glandular disease, and it is most common in those younger than 2 years of age.[12,13] Less often, rubella infection or toxoplasmosis can produce isolated occipital lymphadenopathy.

Preauricular Nodes

Preauricular nodes drain the lateral eyelid and conjunctivae, along with skin overlying the cheek and temple. Severe conjunctivitis associated with ipsilateral preauricular lymphadenopathy is known as Parinaud or oculoglandular syndrome. Oculoglandular syndrome is a relatively common complication of *B. henselae* infection (i.e., cat-scratch disease), affecting approximately 8% of symptomatic patients (Fig. 20.2).[14] The differential diagnosis also includes tuberculosis, tularemia, and nontuberculous lymph node infection. Chlamydial neonatal inclusion conjunctivitis can appear 5 to 10 days after birth, and lymph node enlargement helps to distinguish it from gonococcal ophthalmia neonatorum.[15]

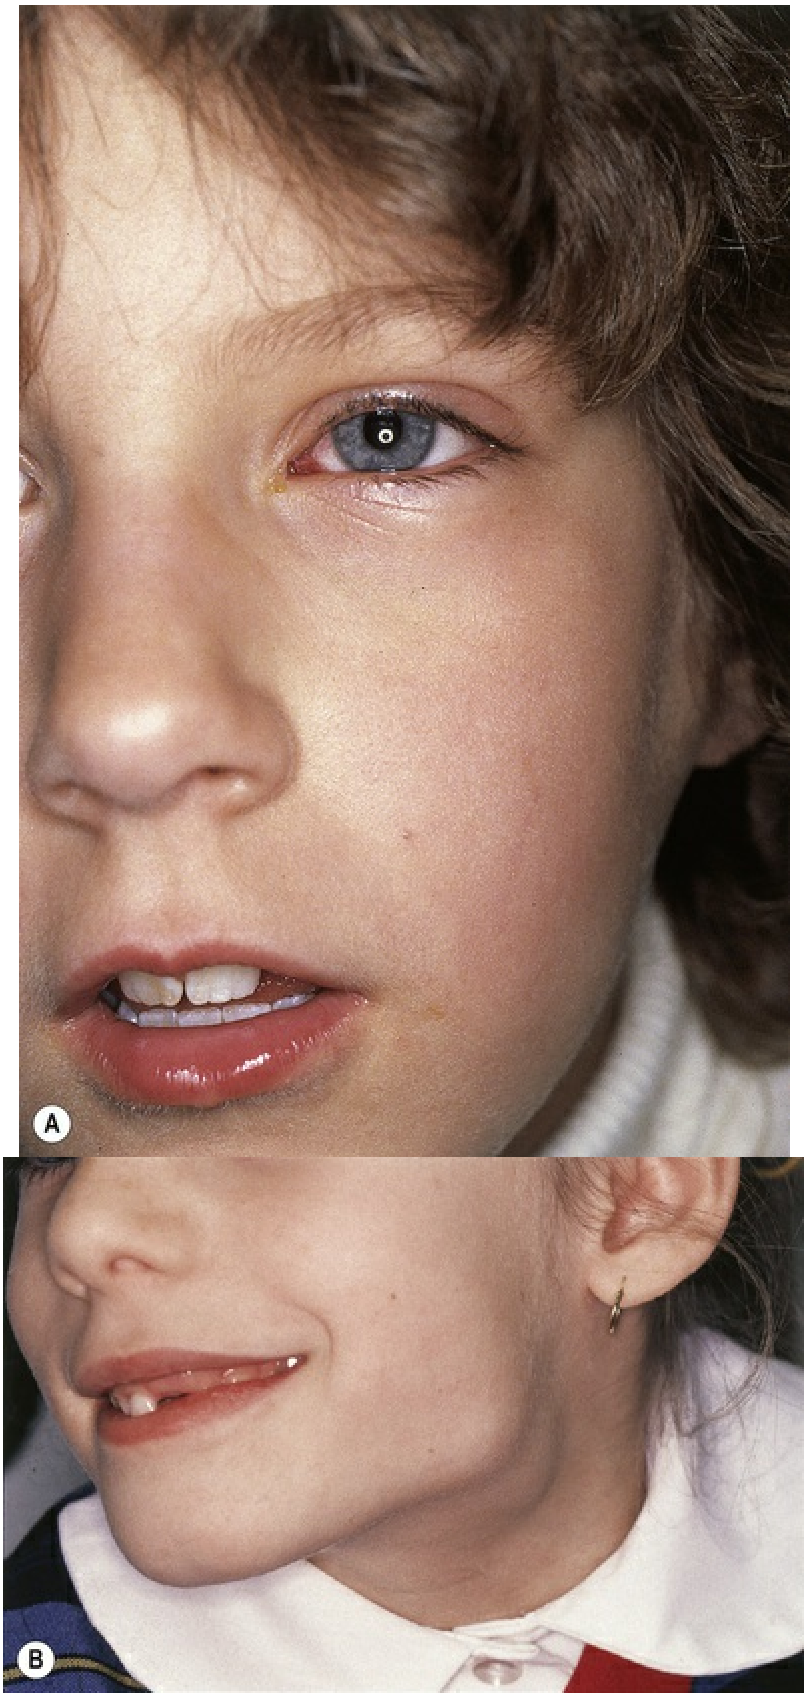

FIGURE 20.2 Two school-aged girls have granulomatous conjunctivitis and lymphadenopathy due to *Bartonella henselae* infection. One girl has associated preauricular lymphadenopathy (A), and the

other has facial and anterior cervical lymphadenopathy (B). (Courtesy of Sarah Long, MD, St. Christopher's Hospital, Philadelphia, Pennsylvania.)

Trachoma, which is a chronic form of chlamydial eye infection, causes an oculoglandular syndrome that can result in blindness. It is rare in the United States but endemic in many developing countries. Epidemic keratoconjunctivitis[16] and pharyngoconjunctival fever[17] are adenoviral infections that can be associated with preauricular adenopathy.

Axillary Nodes

The axillary nodes drain the upper extremity, chest wall, and upper lateral abdominal wall. Localized axillary lymphadenopathy most often represents a response to a pyogenic infection of the upper extremity. *B. henselae* infection is commonly associated with localized axillary lymphadenopathy after a cat scratch on the arm, and rat-bite fever due to *Spirillum minus* can cause axillary node enlargement and tenderness.[18] Regional cutaneous tuberculosis (i.e., scrofuloderma) can be associated with axillary node enlargement.[19,20]

The most common complication of bacille Calmette-Guérin (BCG) vaccination is granulomatous lymphadenitis of the ipsilateral axillary region, which sometimes heals spontaneously but can have a protracted course. Disease responds poorly to isoniazid therapy and can require surgical excision.[21–23] The diagnosis should be considered when evaluating internationally adopted children.

Hidradenitis suppurativa is a defect of terminal follicular epithelium that often affects obese adolescent girls and can lead to recurrent polymicrobial axillary node abscesses, fistulas, and scarring.[24,25] Although gram-positive organisms predominate as causes of axillary skin and lymph node abscesses, *Proteus mirabilis* was an unexpected pathogen in 28% of axillary skin abscesses in adolescent girls in a single-center study.[26]

Noninfectious causes of axillary lymphadenopathy must be considered, because steadily enlarging nodes in the absence of an obvious focus can raise concerns about lymphoma or other neoplasms. Rheumatologic diseases with inflammation of the wrists or finger joints can produce axillary lymph node swelling, although lymphadenopathy usually affects more than the axillary nodes alone.

Epitrochlear Nodes

The epitrochlear nodes drain the distal arm and the middle, ring, and fifth fingers. Isolated enlargement typically results from a local skin lesion infected with *Staphylococcus* or *Streptococcus.* Epitrochlear lymphadenopathy also can follow cutaneous inoculation of *B. henselae, F. tularensis,* or (rarely) *Sporothrix schenckii.* Chronic enlargement of epitrochlear nodes can occur in cases of secondary syphilis and can be a clue to congenital syphilis. Hodgkin disease can manifest with epitrochlear adenopathy.[27]

Iliac and Femoral Nodes

Enlarged iliac nodes can be detected by deep palpation over the inguinal ligament, and enlarged femoral nodes can be detected by deep palpation below the inguinal ligament on the leg in the fossa between the adductor and rectus muscles. Suppurative iliac lymphadenitis is an important cause of retroperitoneal abscess and can result from abdominal trauma, appendicitis, urinary or genital tract infection, or infections of the lower extremity.[28,29] Femoral lymphadenitis results from superficial or deep infection of the lower extremity. *S. aureus* and *S. pyogenes* are implicated most commonly, but *B. henselae* also can cause prominent femoral or iliac lymphadenitis. *Yersinia enterocolitica, Salmonella,* and tickborne *F. tularensis* can infect the inguinal nodes.

The child with iliac lymphadenitis can have fever, a limp, abdominal or hip pain, and spasm of the psoas muscle. The patient typically prefers to lie with the hip flexed and the thigh abducted, because hip extension is extremely painful. Differentiation of iliac lymphadenitis from appendicitis is facilitated by the lack of nausea and vomiting and from pyogenic arthritis by demonstration of a fuller range of motion of the hip on examination.[30] Computed tomography is the favored imaging modality when more extensive evaluation of iliac lymph node abnormalities is required.

Popliteal Nodes

The popliteal lymph nodes are difficult to palpate unless they are substantially enlarged. Consequently, popliteal lymphadenopathy is appreciated only when associated with severe pyogenic infections of the distal lower extremity or knee joint or noninfectious diseases of the reticuloendothelial system.

Management and Therapy

Definitive therapy for localized lymphadenopathy or lymphangitis requires identification of the most likely pathogen involved. A history of antecedent trauma, presence of a skin lesion or infection in the region drained by the involved node or nodes, and rapid development of a large, warm, tender mass is highly suggestive of acute pyogenic lymphadenitis. Needle aspiration of a fluctuant node can provide therapeutic benefit, rapid presumptive diagnosis (with use of Gram stain), and a sample for culture and antibiotic susceptibility testing. Children with nonfluctuant nodes whose symptoms are otherwise consistent with acute bacterial infection can be treated empirically and closely monitored for clinical response. Timely needle aspiration is increasingly important with the rise in community-associated methicillin-resistant *S. aureus* (CA-MRSA) infection. The child with significant fever or systemic symptoms should be further evaluated with a blood culture, complete blood cell count, and measurement of inflammatory markers (e.g., C-reactive protein).

Treatment of acute lymphadenitis should be based on the presumed etiologic agent (Box 20.2). A specimen from the node should be obtained to guide definitive therapy. Because acute pyogenic lymphadenitis can be staphylococcal or streptococcal in origin, the use of a cephalosporin (e.g., cephalexin, 50 mg/kg/day) or clindamycin (30 to 40 mg/kg/day) is appropriate initial therapy for an outpatient. Local prevalence of CA-MRSA and clindamycin resistance by MRSA, methicillin-susceptible *S. aureus* (MSSA), and *S. pyogenes* should be considered.[31–34] Linezolid should be reserved for MRSA infection that is clindamycin resistant. Trimethoprim-sulfamethoxazole is inappropriate for treatment of *S. pyogenes* infection.[35]

Box 20.2

Treatment of Common Infections Associated With Isolated Lymphadenitis

Empiric Therapy

Nafcillin, Cefazolin, Cephalexin, cefadroxil, clindamycin (consider local *Staphylococcus aureus* antibiogram)

Periodontal Abscess

Penicillin V, ampicillin and sulbactam, or clindamycin

Cat-Scratch Disease

Macrolides, rifampin, trimethoprim-sulfamethoxazole (TMP-SMX)

Tularemia

Gentamicin, doxycycline (high relapse rate), ciprofloxacin

Macrolide antibiotics such as erythromycin and azithromycin should not be used to treat acute bacterial adenitis because of the high rate of resistance of *S. aureus,* occasional resistance of *S. pyogenes,* and lack of data supporting use for deeper infections. Azithromycin is an option if cat-scratch infection is considered likely.[36] For patients who appear systemically ill and for young infants at higher risk for a bloodstream infection (BSI), initiation of parenteral therapy with similar agents (e.g., nafcillin or clindamycin, or both, in areas where MRSA and clindamycin resistance of MSSA are prevalent) is indicated.

Nodes with significant suppurative changes are likely to respond more promptly to therapy after percutaneous aspiration or incision and drainage. A total antibiotic (i.e., parenteral plus oral) course of 2 to 3 weeks' duration is often required for complete resolution of bacterial lymphadenitis. In the setting of bacteremia or for life-threatening disease, vancomycin (60 mg/kg/day) should be given, provided normal renal function, in addition to an antistaphylococcal β-lactam and clindamycin after collection of specimens likely to yield a microbiologic diagnosis.[37]

Localized lymph node enlargement lacking the characteristic features of acute pyogenic lymphadenitis and enlarged nodes that do not respond to antibiotic therapy merit further careful evaluation. Any clue regarding possible exposure to unusual pathogens should be pursued diagnostically. A tuberculin skin test (TST) should be performed, realizing that *Mycobacterium tuberculosis* and nontuberculous mycobacterial (NTM) strains can be associated with a positive test result; the latter typically is an intermediate response.

The interferon γ release assay (IGRA) can be used to differentiate between infection due to *M. tuberculosis* and that due to NTM; the test result is negative in the latter case.[38] However, the IGRA is approved for use only in children 5 years of age or older and may not differentiate between *M. tuberculosis* and certain NTM strains, such as *M. kansasii*.[38,39]

B. henselae infection can be evaluated by serologic testing. Cat-scratch lymphadenitis typically is a self-limited infection requiring no antibiotic therapy, but in some cases, antibiotic therapy is beneficial, and aspiration of suppurative nodes may be required. Follow-up is important because unusual systemic complications, such as hepatic involvement and encephalopathy, can occur.[40]

Tularemia can be diagnosed by serologic testing, and initial testing usually is diagnostic if lymphadenopathy has been present for ≥2 weeks (Fig. 20.3). Hidradenitis suppurativa can be temporized by antibiotic therapy such as clindamycin and rifampin, although wide surgical excision is considered most effective, and healing by granulation follows.[41,42]

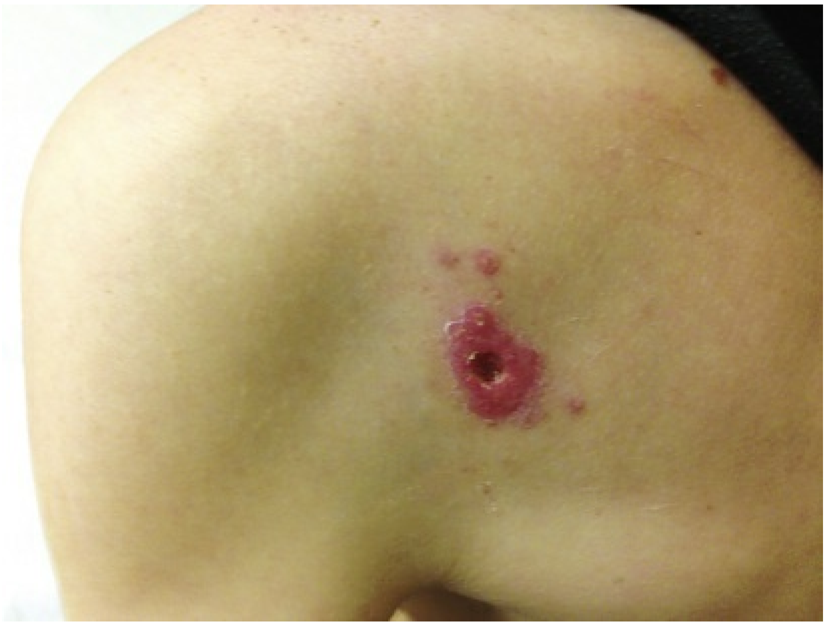

FIGURE 20.3 The shoulder and back of an 8-year-old

boy with ulceroglandular tularemia of the left scapular region and associated axillary lymphadenopathy. The patient had a history of a tick bite of the left scapula. The diagnosis was made by serology. (Courtesy of James Christopher Day, MD, Children's Mercy Hospital, Kansas City, Missouri.)

Biopsy is indicated for patients for whom the history, associated physical findings, and screening laboratory tests fail to lead to a diagnosis, especially when suspicion of a neoplasm or an unusual infection is high. In a series of 75 children who underwent excisional biopsy of a peripheral lymph node, nonspecific reactive hyperplasia was found in 55%, noncaseating granuloma (e.g., cat-scratch disease) in 21%, lymphoreticular malignancy in 17%, and caseating granuloma in 7%.[43] Studies also suggest that fine-needle aspiration, perhaps guided by ultrasound, is a safe and effective alternative to excisional biopsy for discriminating infection from malignancy in the lymph nodes of children; one study found a diagnostic sensitivity of 86% and specificity of 96%.[44–46] However, excisional biopsy should be used in the setting of suspected malignancy and inconclusive aspiration results, and it is the preferred method of therapy in the setting of suspected or presumed NTM infection.[47]

Any specimen from an excised node or needle aspirate should be submitted for Gram staining, acid-fast staining, and culture for bacteria (except when tularemia is suspected and culture poses risk for laboratory personnel), mycobacteria, and fungi. Staining with Warthin-Starry reagents for *Bartonella* is sometimes performed, but a positive result is not specific.

Lymphangitis

Lymphangitis refers to inflammation of subcutaneous lymphatic channels, typically in an extremity. It can manifest an acute bacterial infection or a more chronic, indolent process due to a fungal, mycobacterial, or parasitic pathogen.

Etiologic Agents

Infections that cause lymphangitis are summarized in Table 20.2. *S. pyogenes* is the leading cause of acute lymphangitis. Less commonly, *S. aureus* or other streptococci can cause lymphangitis, as can *Pasteurella* spp. after a cat or dog bite and *S. minor* after a rat bite. When inoculated cutaneously, several organisms can produce chronic, nodular lymphangitic infection.[48,49] Organisms include the dimorphic fungus *Sporothrix schenckii*, *Nocardia* spp., *Mycobacterium marinum*, and certain other mycobacteria, and *Leishmania* spp.[50] In the case of *Nocardia* or NTM, an antecedent history of trauma often is elicited. A foreign body, often wood, can be identified. Arthropod-borne filariasis due to *Wuchereria bancrofti* or *Brugia* spp., which is endemic in the tropics and subtropics, manifests as acute lymphangitic inflammation or chronic lymphatic obstruction with lymphedema.

TABLE 20.2

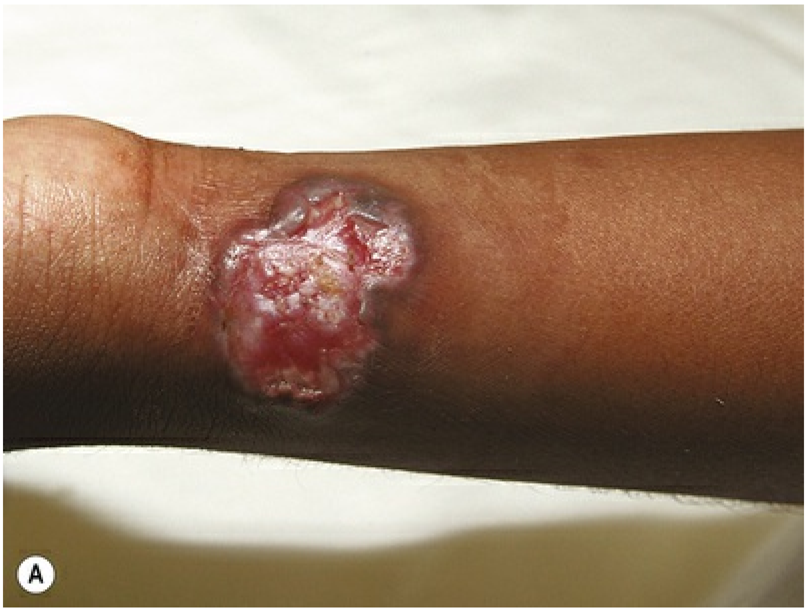
Causes of Lymphangitis

Etiologic Agent	Exposure	Onset	Clinical Features
ACUTE BACTERIAL LYMPHANGITIS			
Streptococcus pyogenes (less commonly, *Staphylococcus aureus*)	Localized skin infection	Acute (<24–48 hr)	Red streaking, tender regional nodes, fever, chills, malaise
Pasteurella multocida	Dog or cat bite	Acute (<24–48 hr)	Red streaking, tender regional nodes, fever, chills, malaise
Spirillum minus	Rat bite	Acute, after incubation period 1–3 wk	Red streaking, tender regional nodes, fever, chills, malaise, headache
NODULAR LYMPHANGITIS (LYMPHOCUTANEOUS SYNDROME)			
Sporothrix schenckii (sporotrichosis)	Soil, peat moss, thorned flowers	Insidious, incubation period 1–12 wk	Inoculation site papule, proximal spread of reddish nodules, systemic symptoms rare
Mycobacterium marinum (occasionally *Mycobacterium chelonae*)	Fish, shellfish, aquariums, ponds	Insidious, incubation period 2–4 wk	Nontender nodules at inoculation site and spreading proximally, systemic symptoms rare
Nocardia brasiliensis	Soil botanicals	Insidious, incubation period 1–2 wk	Localized chronic granuloma with nodular spread, drainage with "sulfur granules," regional adenopathy
Leishmania brasiliensis (also *Leishmania mexicana*)	Travel to endemic area, sandfly bite	Insidious, incubation period 2–8 wk	Primary ulcer with surrounding nontender nodules, no adenopathy or systemic symptoms
Wuchereria bancrofti (also *Brugia* spp.)	Travel to endemic area, mosquito bite	Acute or chronic	Acute: red streaking, adenopathy, fever rare Chronic: lymphatic obstruction, elephantiasis

Clinical Manifestations

Acute bacterial lymphangitis can accompany cellulitis or can occur in association with minor or inapparent skin infection. Lymphangitis is recognized from the rapid appearance of tender, red, linear streaks proceeding from the site of cutaneous (frequently minor) infection toward the regional lymph nodes. Tender lymphadenopathy is typical, as are systemic symptoms such as fever, chills, and malaise. BSI occurs in approximately 5% of patients.[51]

Nodular lymphangitis (i.e., lymphocutaneous syndrome) has distinctive clinical features and expected pathogens.[50] Infection most often manifests on the hands and upper extremities. Sporotrichosis is the prototypical lymphocutaneous infection (Fig. 20.4). The disease often begins with a shallow ulcer at the site of inoculation. Subcutaneous nodules 2 to 20 mm in diameter appear indolently as the infection advances along the course of the lymphatic channel. The nodules are small and freely mobile or adhere to the superficial skin. Larger nodules often exhibit overlying erythema, but they rarely are painful. Nodules sometimes ulcerate, releasing serosanguineous fluid.



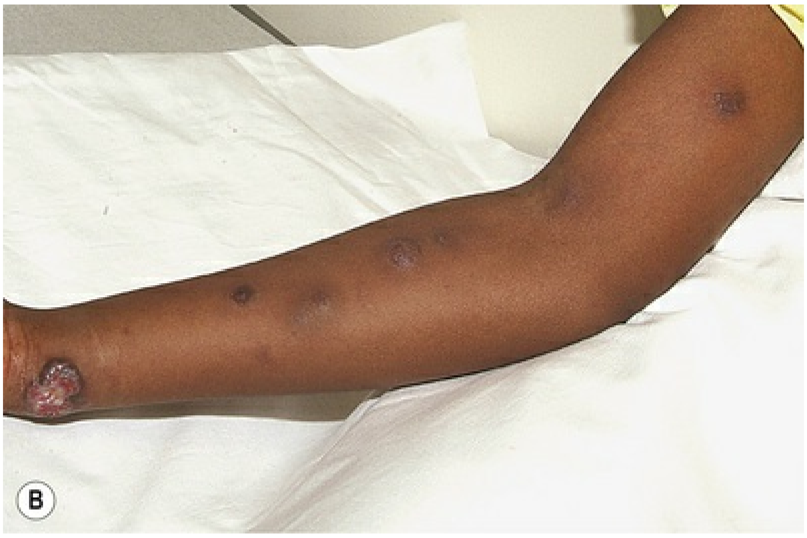


FIGURE 20.4 An adolescent girl had a 4-month history of an ulcerating skin lesion on her wrist (A) and nodular lymphangitis (B). *Sporothrix schenckii* was isolated. Her only exposure to roses was from a florist. (Courtesy of Sarah Long, MD, St. Christopher's Hospital, Philadelphia, Pennsylvania.)

In contrast to acute bacterial lymphangitis, systemic symptoms of infection and regional adenopathy typically are absent in chronic nodular lymphangitis. Most patients do not come to medical attention until several weeks into the clinical illness. Biopsy and culture of lesions establish the diagnosis.

Differential Diagnosis

Acute lymphangitis is a clinical diagnosis made for the febrile patient with tender, linear, red streaking that extends proximally from a site of peripheral infection or traumatic inoculation. Thrombophlebitis is the major differential diagnostic consideration, but it lacks the characteristic inciting lesion unless it is associated with an intravascular cannula and the tender regional lymphadenopathy associated with acute lymphangitis.

The precise etiologic agent (usually *S. pyogenes*) can be identified with a Gram stain and culture of a specimen from the cutaneous lesion or by culture of the blood.[51] Acute lymphangitis develops in about 20% of patients with animal bites infected with *Pasteurella canis* (dogs) or *P. multocida* (cats).[52,53] *S. minus* infection should be considered in a child living in a crowded urban dwelling that is prone to rat infestation because the superficial bite wound often completely heals during the 1- to 3-week incubation period before development of acute lymphangitis.

The origin of nodular lymphangitis usually is established through a careful history of potential exposure to causative pathogens. The incubation period between inoculation and development of lymphangitic nodules can vary from 1 to 8 weeks, depending on the infecting organism.[49,54] *S. schenckii* is found in soil and botanical debris, and infection follows contact with thorned material such as rose bushes or with sphagnum moss.[55] *M. marinum* is a ubiquitous organism in marine and freshwater environments, aquariums, and swimming pools. A reddish blue primary lesion develops at the site of trauma (e.g., fingers and hands in fish-handlers′ granuloma, elbows or knees in swimming-pool granuloma). Ulceration with purulent drainage can occur, and the disease can spread centripetally to produce sporotrichoid-like nodular lymphangitis.[56] The rapidly growing soil and water mycobacterium *M. chelonae* can produce a similar constellation.[57]

Nocardia brasiliensis can gain access to lymphatics through minor wounds contaminated with soil and can produce nodular lymphangitis with suppurative ulceration, occasionally accompanied by regional adenopathy and systemic symptoms.[58] New World cutaneous leishmaniasis is a protozoal disease seen in travelers to rural Central or South America who encounter its sandfly vector. After development of a shallow ulcer at the location of the insect bite, nodular lymphatic spread with superficial scale, discharge, and crusting is common.[59]

The histopathologic changes associated with chronic nodular lymphangitis typically are granuloma formation with epithelioid and giant cells and various degrees of neutrophilic infiltration. Diagnosis of sporotrichosis is made by identification of fungal spores surrounded by eosinophilic material (i.e., asteroid bodies) or inoculation of a specimen from tissue drainage on Sabouraud agar. *M. marinum* often is not detected on acid-fast staining of lymphatic biopsy specimens, but culture on appropriate media incubated at 30°C is highly sensitive. *Nocardia* species appear as delicate, beaded, branching, gram-positive bacilli that can be grown on simple media but may take several days to display characteristic colonial morphology.[60] Pathognomonic sulfur granules are sometimes seen in exudate from lesions. Diagnosis of cutaneous leishmaniasis is made by direct visualization of amastigotes within histiocytes from a biopsy specimen or scraping.

Therapy

Because *S. pyogenes* is the predominant cause of acute lymphangitis, penicillin is the preferred initial treatment. Children with mild disease can be treated with oral penicillin V (50 mg/kg/day). Patients with *S. pyogenes* disease and concurrent BSI should be treated with intravenous penicillin G (100,000 to 400,000 U/kg/day), depending on illness severity; resistance to penicillin has never been documented. Penicillin is also the drug of choice for *Pasteurella* lymphangitis and *S. minus* rat-bite fever. Those with prominent systemic symptoms and unknown or possible bacteremia should receive intravenous therapy with an antibiotic that also provides adequate coverage for *S. aureus*.

Lack of familiarity with the syndrome of nodular lymphangitis often leads to delays in the correct diagnosis and inappropriate antibiotic therapy directed at pyogenic bacteria. Conservative measures, such as local application of a heating pad, may contribute significantly to resolution of lesions associated with sporotrichosis, *M. marinum* infection, or cutaneous leishmaniasis. Itraconazole (100 to 200 mg/day) is the drug of choice for lymphocutaneous sporotrichosis, supplanting saturated solution of potassium iodide (SSKI) because of lower toxicity.[54] Treatment should be continued for 4 weeks beyond resolution of lesions (i.e., 2 to 3 months total).

Antimicrobial agents (e.g., trimethoprim-sulfamethoxazole, minocycline, rifampin plus ethambutol) are variably effective against *M. marinum* lymphangitis, and surgical excisional debridement often is required. *Nocardia* infection usually responds readily to a sulfa drug; amoxicillin-clavulanate is an option for patients allergic to sulfa, and linezolid has been used successfully in some cases. Cutaneous leishmaniasis often heals spontaneously with topical care, but therapy with pentavalent antimony should be used if lesions evolve to the mucocutaneous form.

Respiratory Tract Symptom Complexes

Kathleen A. McGann, Sarah S. Long

Mucopurulent Rhinorrhea

Mucopurulent rhinorrhea (i.e., purulent nasal discharge) denotes nasal discharge that is thick, opaque, and colored.[1] It occurs at any age and usually is a manifestation of a self-limited and uncomplicated viral upper respiratory tract infection (URI). Mucopurulent rhinorrhea is most problematic in children younger than 3 years because of a protracted course and frequent recurrence, especially in those in out-of-home childcare[2]; parental concern and misperception about the cause; and overprescription of antibiotics by healthcare providers.[3–5] Occasionally, this symptom is a clue to the diagnosis of a treatable bacterial infection or underlying condition.

Acute, sporadic mucopurulent rhinorrhea has an infectious cause and almost always is the manifestation of a viral upper respiratory tract infection or the uncomplicated common cold due to rhinoviruses, coronaviruses, human metapneumovirus (MPV), influenza, enteroviruses, parainfluenza, respiratory syncytial virus (RSV), or other circulating viruses.[6,7] When the problem is chronic or recurrent or persistent and unilateral, broader underlying anatomic, obstructive, immunologic, and allergic disorders are considered (Table 21.1).[8–10] Onset in an infant younger than 3 months heightens suspicion of an anatomic anomaly, ciliary dyskinesia, or cystic fibrosis. Accompanying sinusitis, otitis media, or pneumonia at this young age prompts consideration of an immunologic deficiency, especially humoral immunodeficiency (e.g., hypogammaglobulinemia, agammaglobulinemia, human immunodeficiency virus [HIV] infection); neutrophil defect; cystic fibrosis; or ciliary dyskinesia. URIs are conspicuously severe in such instances, with recrudescence occurring almost immediately after discontinuation of antibiotic therapy. Unilateral nasal discharge and obstruction should prompt investigation for a foreign body, mass lesion, or unilateral posterior choanal atresia.

TABLE 21.1
Causes of Mucopurulent Rhinorrhea

Acute	Chronic or Recurrent	
	Underlying Conditions	**Obstructing Lesions**
Viral nasopharyngitis Bacterial sinusitis Acute otitis media Streptococcal nasopharyngitis Anaerobic bacterial nasopharyngitis (nasal foreign body) Adenoiditis Syphilis Pertussis Cerebrospinal fluid rhinorrhea[b]	Allergy[a] Medications or rhinitis medicamentosa[a] (antihypertensive drugs, oral estrogens, α_1-adrenergic agonists, aspirin and nonsteroidal anti-inflammatory drugs) Cocaine use[a] Pregnancy[a] Hypothyroidism[a] Immunoglobulin deficiency Human immunodeficiency virus (HIV) infection Cystic fibrosis Ciliary dyskinesia	Polyps Congenital nasal anomalies (choanal atresia or stenosis, Tornwaldt cyst, deviated septum) Neuroembryonal mass (dermoid, encephalocele, glioma, teratoma) Tumor (hemangioma, angiofibroma, neurofibroma, lipoma, craniopharyngioma) Neoplasm (lymphoma, rhabdomyosarcoma, nasopharyngeal carcinoma)

[a] Rhinorrhea is characteristically clear, but an opaque, white discharge is not unusual.

[b] Rhinorrhea is characteristically clear.

Table 21.2 shows differentiating features of important or common causes of acute mucopurulent rhinorrhea. Allergic rhinitis is included because of its place in the differential diagnosis for older children and adolescents.

TABLE 21.2
Differentiating Among Causes of Nasal Discharge

Characteristic	Viral Nasopharyngitis	Acute Bacterial Sinusitis	Streptococcal Nasopharyngitis	Foreign Body–Related Bacterial Rhinitis	Allergic Rhinitis
HISTORY					
Peak age	Peak in first 2 yr after enrollment in childcare or school	Any	<3 yr	<3 yr	>2 yr
Onset	Acute; dryness, burning in nose or nasopharynx	Insidious with cough day and night or with secondary fever or worsening upper respiratory tract infection symptoms; occasionally, acute, febrile, toxic	Insidious; occasionally acute, febrile, toxic	Insidious	Can be sea or perenni precipitant often ident
Associated symptoms	Nasal congestion, sneezing, malaise	Malodorous breath; head or facial pain, edema		Malodorous breath ± hyponasal voice	Sneezing; congestion nasal itchi postnasal drip/coug allergic conjunctiv with itchi and tearin
Fever	Yes/no	No/yes	Low/high	No	No
Duration of discharge	3–15 days	≥10 days	>5 days	Chronic	Seasonal o perennial
PHYSICAL EXAMINATION					
Associated findings	Red, excoriated nares; sometimes acute otitis media	Periorbital swelling, facial tenderness; mucopurulent postnasal discharge	Anterior cervical lymphadenitis; impetiginous lesions below nose	Mouth-breathing	Transverse nasal or lo eyelid crea infraorbita edema and darkening, conjunctiv cobbleston of conjunc or posterio pharynx
Character of discharge	Clear or colored, watery or thick	Thick, colored	Thick, colored	Unilateral, purulent, putrid bloodstained	Watery, cl
Rhinoscopy	Hyperemic mucosa; dry or glazed early, edematous later; crusted discharge	Normal mucosa; discharge from middle meatus	Normal, hyperemic, or excoriated mucosa	Identifiable object (button, pit, nut), boggy mass (vegetable), or rhinolith	Pale or blu edematous turbinates
DIAGNOSIS					

Diagnostic tests	None; nasal smear shows neutrophils and mononuclear cells ± inclusion bodies, pyknotic epithelial cells	None unless suppurative complications suspected	Nasopharyngeal culture for *Streptococcus* only	Rhinoscopy	Positive allergen sk tests or ser IgE levels, rhinoscop nasal smea rare cases
ETIOLOGY					
Causes	Multiple agents, depending on age and season	*Streptococcus pneumoniae, Haemophilus influenzae, Moraxella catarrhalis*	*Streptococcus pyogenes*	Normal nasopharyngeal facultative and anaerobic bacteria	Allergens
TREATMENT					
Therapies	Saline nasal drops, humidification; antibiotic only for secondary bacterial infection (acute otitis media or sinusitis)	Amoxicillin; amoxicillin-clavulanate (14:1 formulation), 90 mg/kg/day of amoxicillin component	Penicillin V	Removal of obstruction; amoxicillin-clavulanate for tissue or sinus complication	Allergen avoidance; glucocorti nasal spra antihistam antihistam nasal spra leukotrien receptor antagonist nasal salin irrigation, allergen immunoth

Causes

Viral Nasopharyngitis

In uncomplicated viral nasopharyngitis or rhinitis, the nasal discharge initially is clear but can become white, yellow, or green due to mucous secretions, dryness, blood, exfoliation of damaged epithelial cells and cilia, and a leukocytic inflammatory response. High fever and persistence of discharge can be seen, depending on the specific viral agent, but they are more common in uncomplicated infection than generally perceived.

In a study of hospitalized children, more than 50% with uncomplicated adenovirus, influenza, parainfluenza, or RSV infection had temperatures greater than 39°C, and 12% had temperatures greater than 40°C; the height of fever in these children was not different from that in children with serious bacterial infection.[11] Fever persisted for 5 or more days in 37% of the children in the study; 20% to 30% of those with adenovirus or influenza A infection had fever for ≥7 days. In another study, nasal discharge or congestion associated with uncomplicated URI persisted for 6.6 days in 1- to 2-year-old children who were in home care and for 8.9 days in children younger than 1 year in out-of-home childcare.[1] In a systematic review of studies on the common cold and nonspecific URIs in children, symptoms resolved in 50% by day 10 and 7, respectively, and in 90% by days 15 and 16.[12,13]

The bacteriology of nasopharyngeal flora in children with uncomplicated viral respiratory illnesses, mucopurulent rhinorrhea, acute otitis media, and sinusitis has been evaluated and compared with that in healthy children.[6,14–21] Viral infection is associated with acquisition of new serotypes of *Streptococcus pneumoniae* and with temporally increased risk of acute otitis media.[20] Quantitative and some qualitative differences in nasopharyngeal flora have been found in children with purulent nasopharyngitis during uncomplicated viral URIs, with excessive isolation rates reported for *S. pneumoniae* and *Haemophilus influenz*ae, *Peptostreptococcus* spp., *Fusobacterium* spp., and *Prevotella melaninogenica.*[14,18,19] Differences may reflect new bacterial acquisition or exuberant proliferation in virus-induced inflammatory mucus or availability of a more robust specimen than in healthy subjects. A high rate (25%–46%) of isolation of *S. pneumoniae* does not exceed that in healthy young children when fastidious technique is used.[21]

In a prospective study, there was no difference in the duration of illness or complications in children with clear or purulent nasal discharge.[15] A large Cochrane meta-analysis concluded no benefit of antibiotic therapy in children with URI or cough.[5,22] In a placebo-controlled, blinded study of 142 children 3 months to 3 years old with mucopurulent rhinorrhea of any duration, antibiotic therapy (e.g., cephalexin) or systemic use of an antihistamine-decongestant, or both, had no effect on the course or complications of mucopurulent rhinorrhea.[14] In a meta-analysis of randomized, controlled trials assessing the effect of probiotics on URIs in children and adults, significantly fewer days of illness and absences from childcare, school, or work occurred in those receiving a probiotic (i.e., *Lactobacillus* or *Bifidobacterium* strains) compared with placebo.[16]

Acute bacterial adenoiditis has been postulated as a cause of purulent nasal discharge when tympanic membranes are normal, *S. pyogenes* is not found in culture specimens, and radiographs show an enlarged adenoid shadow but no sinus abnormality.[23] No study has been performed to validate this entity. Mucopurulent rhinorrhea plus additional clinical features, such as prolonged or new fever, cough or ill appearance; stridor or auscultatory abnormalities can indicate another diagnosis.

Bacterial Sinusitis

Bacterial sinusitis reportedly complicates 5% to 10% of viral upper respiratory tract infections in children.[24] In a prospective study of 236 children 4 to 7 years of age, 8.8% of symptomatic URIs were complicated by sinusitis using the definitions that follow; all episodes met one of the first two definitions.[13] Mucopurulent rhinorrhea or daytime cough (which frequently is worse at night), or both, of 10 or more days′ duration without improvement, worsening symptoms (i.e., recrudescence after improvement or new onset of fever), or severe onset of symptoms with fever of 39°C or higher and purulent nasal discharge for at least 3 consecutive days strongly suggests paranasal bacterial sinusitis and response to antibiotic therapy.[25–27]

Guidelines on the diagnosis and management of acute bacterial rhinosinusitis have been published.[24,26,27] Sinus radiographs show significant abnormalities in almost 90% of children 2 to 6 years old and many older children with uncomplicated upper respiratory tract illness, supporting a clinical approach to diagnosis without imaging.

Streptococcal Nasopharyngitis

In children younger than 3 years of age, *S. pyogenes* can be associated with high fever, toxicity, and rhinorrhea or indolent infection with irregular fever and purulent nasal discharge, sometimes with associated excoriation of nares or tender anterior cervical lymphadenitis.[13,18,25] In a streptococcal outbreak studied in a childcare facility for school-aged and young children, 26% of children younger than 3 years of age were affected, but pharyngitis was predominant, with no case of nasal streptococcosis.[28]

Other Infectious Causes

Bacterial nasopharyngitis associated with a nasal foreign body is typified by the young age of the patient and putrid, commonly bloodstained, unilateral nasal discharge. Fever is unusual unless infection has spread to contiguous sinuses or distant sites. *Prevotella, Fusobacterium,* and *Peptostreptococcus* spp., as well as facultative flora, are responsible. Nasal discharge can be the first manifestation of congenital syphilis and a later finding in nasal diphtheria, in which discharge is putrid and sanguineous with pieces of pseudomembrane.

Allergic Rhinitis

Allergic rhinitis is uncommon before 2 years of age. Diagnosis can be suspected because of the season, environmental precipitants, personal and family history of allergy or atopy, other associated symptoms, physical findings, and the response to specific interventions, such as avoidance or pharmacotherapy (see Table 21.2). Nasal secretions typically are clear.

Management

For most children with purulent nasal discharge (even if thick and green) of up to 1 week's duration, the history and setting of illness, associated symptoms, and physical findings suggest an uncomplicated viral URI. Antimicrobial therapy is inappropriate unless acute otitis media or sinusitis is diagnosed from additional findings.[5] Symptomatic therapy with saline nose drops or lavage facilitates expulsion of secretions and provides humidification. Its effectiveness reduces parental pressure to prescribe an antibiotic.[29] Over-the-counter medications should be avoided for children, especially those younger than 6 years of age. Antipyretic or analgesic medication is appropriate for the treatment of fever and discomfort.

If mucopurulent rhinorrhea persists for more than 5 days, especially if the epidemiology or certain findings (e.g., anterior cervical lymphadenopathy, scarlatiniform rash, excoriation around nostrils) heighten the likelihood of streptococcal disease, nasopharyngeal specimens should be obtained for the culture of *S. pyogenes* only. If the culture is positive, penicillin V is given for 10 days. Routine culture for or recovery of *S. pneumoniae, H. influenzae, Moraxella catarrhalis,* or *Staphylococcus aureus* has no meaning and can result in misinterpretation.

If mucopurulent rhinorrhea persists for 10 or more days without diminution, especially if other symptoms are present, paranasal sinusitis is likely. Nasal mucosa is examined after use of a single or second (i.e., 5 minutes after the first) application of a topical vasoconstrictor such as oxymetazoline. If purulent secretions flow from the middle meatus, the diagnosis of acute sinusitis is confirmed. Signs of allergic rhinitis can also be confirmed. An imaging study such as contrast-enhanced computed tomography is performed if suppurative complication of sinusitis is suspected.[26,27]

Patients fulfilling a definition of sinusitis are treated with a high-dose (90 mg/kg/day) of amoxicillin with or without clavulanate as first-line therapy, which has been shown to decrease the duration of symptoms.[30] When antimicrobial therapy is effective, substantial improvement of symptoms is expected within 48 to 72 hours. Therapy is continued for 10 to 14 days in children and at least 1 week after resolution of symptoms.[26]

Stridor

Characteristics

Stridor is a rough, high-pitched, monophonic sound caused by passage of air through a narrowed upper airway, which includes the extrathoracic trachea, larynx, and hypopharynx. Because the extrathoracic airway normally narrows during the inspiratory phase of respiration, stridor due to upper-airway disease occurs during inspiration or is more pronounced during inspiration if severe narrowing causes obstruction during inspiration and expiration. Because the intrathoracic trachea normally narrows during expiration, obstruction of the intrathoracic trachea, as occurs with extrinsic compression from a vascular ring or sling or intraluminal obstruction from a foreign body, inflammation, or tracheomalacia, causes a loud noise that is acoustically like stridor and heard during both phases of respiration, but it is more pronounced on expiration. Extrathoracic obstruction (i.e., inspiratory stridor) is associated with prolonged inspiration and underaeration of the chest, whereas intrathoracic obstruction (i.e., expiratory stridor or wheezing) is associated with prolonged expiration and an overinflated chest.

Stridor can be associated with mild tachypnea, but a respiratory rate higher than 50 breaths/min should not be ascribed to upper airway obstruction alone. The degree of obstruction associated with stridor can range from minimal to life-threatening.[31]

The timbre of the stridulous sound provides a clue to the cause. For example, a high-pitched, fixed, dry sound is associated with congenital subglottic stenosis; a wet, rhonchal changing sound with inflammatory laryngotracheitis; and a low-pitched, vibratory, positionally variable sound with laryngomalacia. Associated voice changes also are useful in specifying disease. Vocal cord paralysis causes a weak, dysphonic cry, supraglottic obstruction causes a muffled voice, and laryngotracheitis causes hoarseness or aphonia, frequently with a barking cough.

Etiology

Categorization of the setting and duration of stridor as acute, persistent, or recurrent/episodic provides a framework for considering likely causes (Table 21.3).[31–34] Infections cause most acute upper airway obstruction by means of intraluminal, epithelial inflammation or by encroachment on the airway by reactive or infected lymphoid tissue in parapharyngeal or paratracheal spaces. Viral laryngotracheitis is the most common cause of abrupt-onset stridor in young children.[31] Fungal or viral tracheobronchitis must be considered when stridor occurs in an immunocompromised child; odynophagia and dysphagia also are common.[32]

TABLE 21.3

Causes of Upper-Airway Obstruction and Stridor

Acute	Persistent
INFECTIOUS	**CONGENITAL**
Viral laryngotracheitis (croup) Bacterial tracheitis Epiglottitis, supraglottitis Peritonsillar, retropharyngeal, or parapharyngeal abscess Tracheobronchitis associated with immunodeficiency	Laryngotracheal web, cleft, cyst, hemangioma Tracheal stenosis Vascular ring or sling Laryngotracheal malacia Neuromuscular disorder Cystic hygroma
NONINFECTIOUS	**ACQUIRED**
Angioedema Anaphylaxis	Posttraumatic tracheal stenosis Subglottic stenosis

Foreign body Necrotizing tracheobronchitis in neonates Recurrent/episodic spasmodic croup Caustic burns Gastroesophageal reflux	Foreign-body aspiration Mediastinal mass (tumor, lymphatic, vascular) Papilloma (perinatally acquired) Posttraumatic spinal cord, vagal or glossopharyngeal nerve, or vocal cord damage Vocal cord dysfunction or paralysis Bulbar neuropathy (infectious, postinfectious, malignant) Eosinophilic esophagitis

Congenital anatomic abnormalities should be considered, especially for infants whose persistent stridor began neonatally. Acquired obstruction can have an abrupt onset and an obvious cause (e.g., foreign body aspiration, necrotizing tracheobronchitis in ventilated neonates) or more insidious onset and an inapparent cause (e.g., expanding laryngotracheal papillomas or hemangioma, an extrinsic compressing mass). The younger the infant, the more likely that sudden obstruction, apnea, or feeding difficulties overshadow a singular complaint of stridor.

Clinical Features of Acute Infectious Causes

Recognition, avoidance of precipitating sudden airway occlusion, and urgent, expert intervention to establish an airway when indicated are paramount to avert disastrous outcomes of acute upper airway obstruction. Table 21.4 shows characteristic features of infectious causes of stridor and acute airway obstruction.[35–42] Viral laryngotracheitis (i.e., infectious croup) or laryngotracheobronchitis due to parainfluenza viruses, especially type 1, is by far the most common.[35,36] Influenza viruses, RSV, adenoviruses, measles, MPV, and other viruses typically cause symptomatic disease elsewhere in the respiratory tract, but during epidemic seasons, stridor is the predominant feature in a minority of infected children.

TABLE 21.4

Differentiating Infectious Causes of Upper Airway Obstruction

Characteristic	Viral Laryngotracheitis	Epiglottitis or Supraglottitis	Bacterial Tracheitis	Retropharyngeal Abscess
HISTORY				
Peak age	6–36 mo	<6 yr, any	2–4 yr, any	2–4 yr
Peak season	Late fall, late spring	Any	Fall, winter; any	Any
Prodrome	Viral illness	Uncommon	Viral illness	Uncommon

Onset of stridor	Gradual	Abrupt	Abrupt	Abrupt
PHYSICAL EXAMINATION				
Peak temperature (°C)	38–39	>39	>39	>39
Predominant findings	Brassy or barking cough, stridor	Toxicity, stridor	Toxicity, stridor	Toxicity, stridor
Associated findings	Bark, rhinorrhea	Sore throat, odynophagia, dysphagia, anxiety, drooling	Brassy cough, anxiety	Lethargy, dysphagia, drooling, trismus
Voice	Hoarse, raspy	Normal, muffled, mute	Hoarse, raspy	Muffled, mute
Position	Any; thrashing	Tripod or sniffing position; stillness; refusing to lie flat	Any; thrashing	Sniffing position; stillness; reluctance to move neck
Airway occlusion	Predictable from degree of stridor	Sudden	Sudden	Sudden
Response to racemic epinephrine	Yes, with rebound	No	No or partial	No
LABORATORY TESTS				
Peripheral neutrophils	Normal or low	High	Immature	Immature
RADIOGRAPHY				
Hypopharynx	Distended	Distended	Distended	Anteriorly displaced
Airway	Subglottic narrowing steeple sign; edema cords	Enlarged epiglottis (thumb sign) and aryepiglottic folds	Subglottic narrowing; irregular trachea ± intraluminal membranes	Prevertebral soft tissue mass with anterior displacement of airway (not valid sign for expiratory film, flexed neck)
ENDOSCOPY				
Examination findings	Red, edematous subglottis and lateral tracheal walls; crusting pseudomembrane	Red, edematous supraglottic structures	Red, edematous, eroded trachea and bronchi; thick purulence, pseudomembrane	Bulging mass in posterior pharyngeal wall; purulence
ETIOLOGY				
Agents	Parainfluenza viruses, especially type 1 (epidemic); other viruses (sporadic)	*Streptococcus pyogenes*, *Streptococcus pneumoniae*, *Haemophilus influenzae* b and other *Haemophilus* spp., *Staphylococcus aureus*	*Staphylococcus aureus*, *Streptococcus pyogenes*, *Streptococcus pneumoniae*	*Streptococcus pyogenes*; *Staphylococcus aureus*; rare *Streptococcus pneumoniae*; other oral flora

Bacterial tracheitis usually is a complication of viral laryngotracheitis (with concordant peak age and season) but can occur at any age or as a complication of oropharyngeal surgery.[43] *S. aureus* is the most common cause, followed by *S. pyogenes;* the role of anaerobic bacteria is less clear.[41,43] With the universal use of *H. influenzae* b vaccine, epiglottitis is a rare cause of stridor; current cases of supraglottitis are more likely to affect the aryepiglottic region and to be caused by streptococci and staphylococci. Other agents, including *Fusobacterium* spp. and other anaerobes that can cause parapharyngeal and retropharyngeal infections in children, must be considered because the incidence is increasing[42,44,45] (see Chapter 28).

The history surrounding the onset of stridor and the patient's age and examination findings are the most helpful clues to the likely site and cause of infection. The child with viral laryngotracheitis usually has had 2 to 3 days of a typical URI when cough worsens and stridor begins. The child with bacterial tracheitis usually has had a similar background illness and then has sudden onset of high fever, toxicity, and rapid progression to airway obstruction. The young child with retropharyngeal abscess or adolescent with peritonsillar abscess has less stridor but refuses to swallow and has a muffled voice, reluctance to move the neck, and a guarded posture to maximize oropharyngeal airway patency. Trismus is an expected and useful finding in patients with peritonsillar abscess and some lateral pharyngeal space infections of odontogenic origin.[38] Epiglottitis and supraglottitis cause the patient to guard anxiously in a sitting posture with arms back, jaw forward, and chin raised (i.e., sniffing position) to maximize lift of the epiglottis away from the airway. In contrast, subglottic, tracheal obstruction cannot be lessened by position; patients with laryngotracheitis or bacterial tracheitis thrash about with the anxiety of suffocation.

The expected course[36,46,47] and sequelae of acute infectious airway obstruction are shown in Table 21.5. Children with viral laryngotracheitis are less prone to sudden complete obstruction; the hourly course is predictable by degree of stridor and adequacy of aeration. The response to racemic epinephrine and dexamethasone therapy usually averts intubation.[48] In a systematic review of children with croup, symptoms resolved in 2 days for 90%.[12] Establishment of an artificial airway is urgently required for almost all patients with stridor due to acute supraglottitis and bacterial tracheitis and for many with retropharyngeal infection. The course of disease in children with bacterial tracheitis can be further complicated because infection (and obstructive consequences) commonly extends the length of the trachea and below.

TABLE 21.5

Expected Course and Sequelae of Acute Infectious Upper Airway Obstruction

Characteristic	Viral Laryngotracheitis	Supraglottitis, Epiglottitis	Bacterial Tracheitis	Retropharyngeal Abscess
Artificial airway (% of cases)	<1	>90	>75	<50 to >75[a]
Median intubation period	4 days	2 days	6 days	2 days
Airway occlusion after intubation	Rare	No	Yes	No
Death during hospitalization	No	No	Yes	No
Airway sequelae (% of cases)	<3	Rare	<3	No

[a] Varies according to age and site (e.g., higher retropharyngeal; lower in older, parapharyngeal and surgical drainage)

Cough

Characteristics

Cough is a critical protective mechanism to expel particulate matter from the larynx and trachea and is a cardinal sign of infectious and noninfectious respiratory tract and nonrespiratory tract disorders. Occasional acute, life-threatening infectious and noninfectious causes may be overlooked unless the clinician adopts a disciplined diagnostic approach. Careful assessment of a pathologic cough—its onset, duration, clinical context, association with other findings, specific timbre, pattern, and productivity—frequently predicts the site of pathophysiology and narrows the differential diagnosis to a limited number of entities.

Cough usually is defined as acute (<3 weeks), subacute (3–8 weeks), or chronic (>8 weeks). A wet or moist cough in children, frequently referred to as *productive*, is associated with detectable secretions by bronchoscopy and can be reported accurately by parents and clinicians.[47]

Etiology

A dry cough is expected in allergic rhinitis/sinusitis and asthma, and a wet cough is typical in infectious sinusitis, bronchiolitis, bronchiectasis, and pneumonia. In a systematic review of self-limited URIs, acute cough symptoms resolved by day 10 after onset in 50% and by day 25 after onset in 90% of children.[12] Isolated subacute cough (in absence of other symptoms), which usually is dry and follows a viral infection, frequently is related to increased cough receptor sensitivity.[49] Chronic cough (≥8 weeks) is pathologic. If the durations of 4 to 8 weeks are included, many coughs are postinfectious and resolve spontaneously.[50–52]

The differential diagnosis can be focused by age, history, and clinical findings. The algorithms for sequential evaluation and management sometimes are complex[50,51,53,54] and best performed by a pediatric pulmonologist. Most common causes of chronic cough in older children are allergic or nonallergic rhinitis and sinusitis, asthma, protracted bacterial bronchitis, and gastroesophageal reflux disease.[50–56] An important minority of children have cystic fibrosis, non– cystic fibrosis bronchiectasis, immunodeficiency disorders, or ciliary dyskinesia. These diagnoses are considered especially in the preschool-age child with chronic cough.[53]

Management focuses on determining the cause. No evidence supports the use of medications aimed at symptomatic relief of acute or chronic cough, and some data suggest harmful effects are possible.

Cough should not be accepted as a sign of a self-limited URI in infants younger than 3 months of age. The mnemonic CRADLE, which is used to recall the differential diagnoses for cough in infants,[57] refers to cystic fibrosis (C); respiratory tract infections (R), especially pneumonia and pertussis; aspiration (A) due to swallowing dysfunction, gastroesophageal reflux, or tracheoesophageal fistula; ciliary dyskinesia (D); lung, vascular, or airway malformations (L); and edema (E) due to heart failure or pulmonary lymphangiectasia.

Table 21.6 provides a framework for consideration of cough illnesses. There is considerable overlap in symptoms of cough caused by certain infectious agents, such as *Bordetella pertussis* or *Mycoplasma pneumoniae* in adolescents[58] because of a common tracheobronchial site of pathophysiology and frequent dual infections.[59] *B. pertussis* causes a dramatic, debilitating, paroxysmal cough without airway or lower tract abnormalities (unless secondary pneumonia occurs, leading to fever and toxicity), whereas *Chlamydia trachomatis* causes pneumonia with prominent tachypnea: the cough is important only because it brings the child to medical attention (see Chapters 162 and 167). Diagnosis of pneumonia is based on signs of lower respiratory tract involvement, such as tachypnea and retractions, in addition to cough, and the likely causative agent is determined from the constellation of clinical findings (Tables 21.7 and 21.8).

TABLE 21.6
Differentiating Among Causes of Cough

Cause	Peak Age	Nature of Cough	Cough as Dominant Feature	Anticipated or Associated Findings
INFECTIONS OF THE RESPIRATORY TRACT				
Viral laryngotracheitis	<5 yr	Brassy, painful	Yes	Hoarse, raspy voice; viral URI complex[a]
Viral laryngotracheitis or laryngotracheobronchitis	6–36 mo	Barking, brassy	Codominant with stridor	Stridor, hoarseness, viral URI complex[a]
Mycoplasma pneumoniae	Adolescent	Hacking, paroxysmal, painful	Yes	Prodromal, fever, headache, myalgia; then gradual worsening cough; crackles
Pertussis	Infancy, adolescence	Sudden paroxysm of explosive, machine-gun bursts (15–30 per breath) when beyond neonatal age	Yes	Bulging, watering eyes during paroxysm, posttussive emesis; skin and conjunctival hemorrhages; afebrile, without lower respiratory tract symptoms or symptoms between paroxysms
Chlamydia trachomatis pneumonia	1–3 mo	Staccato, dry (single cough per breath)	Yes	History can include prior/concurrent conjunctivitis; afebrile, tachypnea, crackles
Bronchiolitis	4 mo–2 yr	High-pitched or grunt	No	Wheezing, rhinorrhea, respiratory distress; ± fever
Pneumonia (bacterial or viral)	Any	Wet, productive or nonproductive	Codominant with respiratory distress	Tachypnea, rales, respiratory distress; fever
Pleurodynia	Any	Inspiratory hitch; expiratory grunt	Codominant with chest pain	Chest pain; costochondral tenderness

Sinusitis	Any	Irritative; occurs during day and worsens at night	Sometimes	Mucopurulent rhinorrhea, postnasal discharge; facial pain, swelling, or tenderness; headache; ± fever
Tracheoesophagitis (fungal or viral)	Any	Irritative	No	Odynophagia or dysphagia; immune-compromised host; hoarseness; oropharyngeal lesions
Cystic fibrosis	<2 yr; any	Wet, productive; paroxysmal, hacking	Sometimes	Poor growth; persistent and recurrent sinusitis, pneumonia; digital clubbing
Protracted bronchitis	Any; mean, 8–9 yr	Wet, productive; >8 wk	Yes	Bronchoscopy; neutrophils, bacteria, cytokines; response to antibiotic
OTHER CONDITIONS				
Purulent pericarditis	Any	Grunt	Sometimes	Fever, toxicity, respiratory distress or dyspnea; displaced point of maximum impulse; muffled heart sounds
Myocarditis	Any	Grunt	Sometimes	Fatigue, dyspnea, tachypnea; ± fever
Congestive heart failure	Any	Grunt, wet, or brassy	Sometimes	Fatigue, dyspnea, sweating, tachycardia, tachypnea; ± fever; distended neck veins, liver
NONINFECTIOUS AIRWAY ABNORMALITIES				
Gastroesophageal reflux	6 wk–6 mo	High-pitched, dry	Codominant with other symptoms	Stridor, choking, gagging, irritability, arching (Sandifer syndrome) ± regurgitation, pneumonia
Reactive airway, asthma	6 mo–adolescence	Irritative dry, repetitive (not paroxysmal); night especially	Sometimes	Atopic, precipitants, seasonal; ± wheezing; response to β-agonist
Congenital vascular rings, pulmonary sling	Infancy	Brassy	No	Stridor; onset of symptoms in first month of life
Compression on airway or glossopharyngeal or phrenic nerve	Any	Irritative, dry	Sometimes initially	Can be positional (tumors, other masses), associated with other neuropathies, stridor, changes in phonation
Habit cough	Adolescence	Vibratory, low-pitched, honking; disappears with sleep	Yes, sole feature	"La belle indifference"; family dynamics and other somatization

[a] Viral upper respiratory tract infection (URI) complex consists of fever, rhinorrhea,

sore throat, conjunctivitis, exanthem, and enanthem.

TABLE 21.7

Symptoms and Signs of Pneumonia

Symptoms	Signs	Physical Examination Findings
Fever	Fever	Crackles (rales)
Cough	Cough	Wheezes (depending on cause)
Rapid breathing	Tachypnea	Diminished breath sounds
Difficulty breathing	Dyspnea	Bronchial (tubular) breath sounds
Vomiting	Retractions	Dullness to percussion
Poor feeding	Nasal flaring	Decreased tactile and vocal fremitus
Irritability	Grunting	Meningismus (upper lobe, bacterial)
Lethargy	Splinting	Ileus (lower lobe, bacterial)
Chest pain	Apnea	Pleural friction rub (pleural fluid)
Abdominal pain		
Shoulder pain		

TABLE 21.8

Clinical Features of Pneumonia in Infants Younger Than 3 Months

Characteristic	Respiratory Syncytial Virus	Other Respiratory Viruses	*Chlamydia trachomatis*	Pertussis[a]
HISTORY				
Season	Winter	Unique to each	Any	Any; peak July–October
Onset	Acute, days	Acute, days	Insidious	Progressive, days
Illness in others	URI	URI, flu, croup	No	Cough
Fever	Half of cases	Most cases	No	No
Cough	Yes	Yes	Yes/staccato	Yes/paroxysmal
Associated features	Apnea, URI	URI, croup, conjunctivitis	Conjunctivitis (prior or current)	Apnea, cyanosis, posttussive emesis
PHYSICAL EXAMINATION				
Predominant feature	Respiratory distress	Respiratory distress	Cough	Cough
General appearance	Ill, not toxic	Ill, not toxic	Well, tachypneic	Well between paroxysms
Degree of illness: respiratory findings	Degree of illness = findings	Degree of illness = findings	Findings > degree of illness	Ill only during cough
Auscultation	Wheezes, coarse crackles	Crackles, wheezes	Diffuse crackles	Clear
LABORATORY STUDIES				
Chest radiograph	Hyperaeration, subsegmental atelectasis, peribronchial	Hyperaeration, ± peribronchial thickening, ± diffuse interstitial infiltrates	Hyperaeration, diffuse alveolar and interstitial infiltrates	Normal or perihilar infiltrate

	cuffing			
White blood cell count	Normal or lymphocytosis	Normal, lymphocytosis, neutropenia	Eosinophilia	Lymphocytosis; no eosinophilia
Other findings	Hypoxemia	—	Increases in IgG, IgA, IgM	—
Diagnostic tests	Nasal wash EIA, DFA, PCR	Nasal wash EIA, DFA, PCR	Conjunctival, NP DFA, EIA	NP, PCR, culture

[a] Pertussis is included in this table because it should be considered in young infants with cough and respiratory distress, although pneumonia is characteristically absent.

DFA, direct fluorescent antibody (test); EIA, enzyme immunoassay; Ig, immunoglobulin; NP, nasopharyngeal specimen; PCR, polymerase chain reaction; URI, upper respiratory tract infection.

Protracted bacterial bronchitis is inadequately studied, but it may be an underdiagnosed cause of chronic wet cough for which antibiotic therapy may be appropriate.[60] Confirmation rests on bronchoscopic findings of dense bacteria and an acute neutrophilic inflammatory response.[61] Because isolated bacteria are those found commonly in oropharyngeal flora, acute otitis media, and sinusitis, some pulmonologists prescribe a diagnostic or therapeutic trial of amoxicillin-clavulanate for 2 weeks for patients with a typical isolated episode of chronic cough.

Tachypnea and Other Signs of Lower Respiratory Tract Disorders

Tachypnea can be a voluntary or involuntary response to anxiety, fright, or pain; an abnormal breathing pattern related to central nervous system dysfunction; or the physiologic response to increased temperature or metabolic state. Most commonly, tachypnea is the response to respiratory acidosis or hypoxemia of acute infection or the attempt to restore pH balance during metabolic acidosis (e.g., diabetes, salicylate poisoning, dehydration). Metabolic causes should not be forgotten while the clinician pursues the much more likely primary pulmonary causes. Tachypnea can result from primary cardiac abnormalities (e.g., congestive heart failure, cyanotic congenital heart disease), pulmonary vascular abnormalities (e.g., cardiac shunts, capillary dilatation, hemorrhage, obstructed return to the heart, infarction), impaired lymphatic flow (e.g., congenital lymphangiectasia, tumor), or pleural fluid collections (e.g., hemorrhagic, purulent, transudative or lymphatic fluid, an infusion from a misplaced vascular catheter).

Clinical practice guidelines for management of community-associated pneumonia in infants and children by the Pediatric Infectious Diseases Society and the Infectious Diseases Society of America include an excellent literature review of clinical findings.[62] Table 21.7 shows symptoms and signs of pneumonia in infants and children. Tachypnea is thought to be the best clinical predictor of lower respiratory tract infection in children. The World Health Organization (WHO) defines pneumonia primarily as cough or difficult breathing and tachypnea. The definition of tachypnea is related to age, with a respiratory rate of >60 breaths/min in infants aged 0 to 2 months, >50 in infants 2 to 12 months, >40 in children 1 to 5 years, and >20 in children older than 5 years of age.[63,64]

Tachypnea has a sensitivity of 50% to 85% for the diagnosis of lower respiratory tract infection and a specificity of 70% to 97%.[65,66] At less than 24 months of age, the younger the patient, the less likely that pneumonia is the diagnosis if tachypnea is absent. In one study, for infants younger than 2 months of age, a respiratory rate of 60 breaths/min, retractions, or nasal flaring had sensitivity for the diagnosis of pneumonia of 91%.[66] In a study from a U.S. emergency department of children younger than 5 years who were undergoing chest radiography for possible pneumonia, respiratory rates in those with or without documented pneumonia did not differ significantly. However, 20% of those with WHO-defined tachypnea had pneumonia confirmed compared with 12% of those who did not.[67]

Obtaining chest radiographs for febrile infants without an apparent focus of infection to exclude pneumonia missed by physical examination has a low yield in the absence of tachypnea.[68,69] Cough is a more sensitive but nonspecific symptom of pneumonia. Other symptoms and signs associated with pneumonia, such as nasal flaring, intercostal retractions, and cyanosis, have lower sensitivity (25%, 9%, and 9%, respectively) but high specificity (87%, 93%, and 94%, respectively).[65] Although fever, cough, and tachypnea are cardinal features, they can be overshadowed or overlooked in patients who come to medical attention for pneumonia-associated stiff neck, abdominal pain, or chest pain or for nonspecific symptoms of illness, such as feeding difficulty in infants. Although a chest radiograph is not routinely needed for children with any of these complaints, it should be considered if the patient has fever and cough or tachypnea.[70,71] Classic symptoms of pneumonia reported in adolescents and adults are fever, chills, pleuritic chest pain, and cough that produces purulent sputum, with less noticeable tachypnea.

Grunting is an expiratory sound produced in the larynx when vocal cords are adducted to generate positive end-expiratory pressure (i.e., self-induced PEEP) and increased resting volume of the lung. Its causes are myriad but never trivial. Grunting can be a sign of surfactant deficiency in the neonate or of pulmonary edema, foreign body aspiration, severe pneumonia, mediastinal mass or severe mediastinal shift from any cause, pleuritic or musculoskeletal chest pain, or myopericarditis or other cardiac abnormalities at any age.[72] Retractions (i.e., intercostal, subcostal, or suprasternal) and grunting have been associated with severe pneumonia, and nasal flaring and head bobbing with hypoxemia.

Adventitial respiratory sounds usually indicate lower respiratory tract disease, pulmonary edema, or hemorrhage. *Wheezes* are continuous musical sounds made predominantly on expiration and are a sign of airway obstruction. Widespread bronchiolar narrowing, as most commonly occurs with the inflammation of virus-associated lower respiratory tract infection, produces heterophonous, high-pitched, sibilant wheezes of variable pitch and presence in different lung fields.[73] Fixed obstruction in a larger airway, as from a foreign body or anomaly, produces a homophonous, monotonous wheeze. The rate of radiographically confirmed pneumonia among children with wheezing is low (<5% overall and 2% in the absence of fever).[70]

Rhonchi, sometimes also called low-pitched wheezes or coarse crackles, are nonrepetitive, nonmusical, low-pitched sounds frequently produced during early inspiration and expiration that usually are a sign of turbulent airflow through secretions in large airways. *Fine crackles,* the term preferred by pulmonologists over *rales* (which has a variety of meanings in different languages) are high-pitched, low-amplitude, end-inspiratory, discontinuous popping sounds indicative of the opening of peripheral air-fluid interfaces. Fine crackle is the auscultatory finding suggesting the diagnosis of pneumonia.

Auscultatory abnormalities of crackles and wheezing have disparate diagnostic usefulness in various studies, depending on the categorization of bronchiolitis. Tachypnea is a more sensitive finding than crackles for bacterial pneumonia; wheezing is more sensitive than tachypnea for bronchiolitis.

Diminished or distant breath sounds, dullness to percussion, and decreased vocal fremitus indicate parenchymal pulmonary consolidation, pleural mass, or fluid collection. *Bronchial* (*tubular*) *breath sounds* have a low-pitched sound of similar intensity throughout inspiration and expiration, as is heard normally in the intrascapular area. Bronchial breath sounds, dullness to percussion, and increased vocal fremitus over an anatomically (tubular) confined lung field indicate parenchymal consolidation, atelectasis, or another continuous tissue or fluid density juxtaposed between a bronchus and the chest wall.

Radiographic infiltrates have been reported in 5% to 19% of children with fever in the absence of symptoms or signs of lower respiratory tract infection.[74,75] Rate of pneumonia deemed occult fell from 15% to 9% after universal vaccination with 7-valent pneumococcal conjugate vaccine (PCV7) in one study.[70] Clinical features associated with occult pneumonia in another study included cough, fever of more than 5 days' duration, fever greater than 39°C, and leukocytosis greater than 20,000 cells/mm^3; only 5% of children without cough had radiographically confirmed pneumonia.[74]

Differentiating Features of Pneumonia

Pneumonia in Young Infants

In young infants, acute infection with bacterial and nonbacterial respiratory tract pathogens frequently leads to lower respiratory tract infection. Except in the first few days of life, when pneumonia predominantly is caused by bacteria acquired from the mother's genital tract or organisms acquired transplacentally, nonbacterial pathogens are overwhelmingly predominant.[72] As perinatally acquired agents persist, community exposures increase, and maternally derived antibody protection wanes, the infant between 3 weeks and 3 months of age is vulnerable to a unique array of lower respiratory tract pathogens.[76]

The clinical setting, specific symptom complex, and severity of illness in proportion to findings on physical examination aid identification of likely causes and guide the diagnostic and therapeutic approach (see Table 21.8). Although the pathogens listed in Table 21.8 frequently are referred to as causing afebrile pneumonia, this is a misnomer because *B. pertussis* infrequently causes lower respiratory tract abnormalities, and RSV and especially other respiratory viruses frequently cause fever.[11,72,77,78] A causal role for *Ureaplasma urealyticum* is not completely defined because the situation is confounded by the asymptomatic presence of this organism in women and young infants. Pneumonia due to *Pneumocystis jirovecii* probably is confined to infants with severe debilitation or immune defects.

Pneumonia in Older Infants, Children, and Adolescents

Table 21.9 categorizes the features of acute pneumonia in older infants, children, and adolescents by cause. No single fact in the medical history or examination finding is unique for any agent, but when taken together, a working diagnosis emerges and guides intervention or further diagnostic testing. Chest radiography and laboratory tests usually are reserved for patients who are ill and hospitalized or whose clinical picture is not compelling for a category of etiologic agents.

TABLE 21.9

Clinical Features of Acute Pneumonia in Children and Adolescents

Characteristic	Bacteria	Virus	Mycoplasma	Tuberculosis
HISTORY				
Age	Any; infants especially	Any	School age	Any; <4 yr and 15–19 yr especially
Temperature (°C)	Most ≥39	Most <39	Most <39	Most <39 (unless empyema)
Onset	Abrupt	Gradual	Worsening cough	Insidious cough
Others in home ill	No	Yes, concurrent; upper respiratory tract infection, rash,	Yes, weeks apart; pharyngitis, flulike illness, cough	Yes, persistent cough

		conjunctivitis		
Associated signs, symptoms	Toxicity, rigors	Myalgia, rash, mucous membrane involvement	Headache, sore throat, chills, myalgia, rash, pharyngitis, myringitis, chest pain	Weight loss, night sweats (late)
Cough	Wet, productive	Nonproductive	Hacking, paroxysmal, usually nonproductive	Irritative or productive
PHYSICAL EXAMINATION				
Predominant feature	Toxicity, respiratory distress	Respiratory distress	Cough	Persistent cough
Degree of illness: respiratory finding	Degree of illness > findings	Degree of illness ≥ findings	Degree of illness < findings	Well: no findings (+ cough); ill with findings
Pleuritic chest pain	No/yes	No	No	No/occasional
Auscultation	Unilateral, anatomically confined crackles or none; dullness, diminished or bronchial/tubular sounds	Diffuse, bilateral crackles, wheezes, rhonchi	Unilateral, anatomically confined crackles; ± wheezes	Most normal; or unilateral crackles ± dullness
LABORATORY STUDIES				
Chest radiograph	Hyperaeration, patchy alveolar infiltrate or consolidation in lobe, segment, subsegment	Hyperaeration, interstitial infiltrate in diffuse or perihilar distribution; "wandering" atelectasis	Patchy alveolar and/or interstitial infiltrate in single or contiguous, usually unilateral lower lobe or lobes; perihilar adenopathy	Patchy alveolar infiltrate in single or contiguous lobes with disproportionate hilar adenopathy; miliary or lobar consolidation
Pleural fluid	No/yes (large)	No/yes (small)	No/yes (small to moderate)	No/yes (small, large)
Peripheral white blood cell count (cells/mm^3)	Most cases >15,000; neutrophils ± bands	Most cases <15,000; lymphocytes	Most cases <15,000; neutrophils	Most cases <15,000; neutrophils, monocytes
Sputum	Copious, purulent; neutrophils, abundant bacteria	Scant mucoid; epithelial, mononuclear cells	Scant mucoid; mixed mononuclear cells/neutrophils	Scant to copious; neutrophils (if copious)
Diagnostic tests	Sputum Gram stain, culture; blood culture	Nasal wash, throat, bronchoscopy specimen for antigen detection, polymerase chain reaction (PCR); acute and convalescent serology	Throat, nasal, bronchoscopy specimen for PCR; cold agglutinins (≥12 years); acute and convalescent serology	Gastric aspirate; sputum stain and culture; tuberculin skin test or interferon γ release assay (IGRA) (≥5 yr old)

Several studies using complex diagnostic methods have confirmed the specific cause of pneumonia in 45% to 85% of cases.[77–81] Viral causes predominate, and most are amenable to diagnosis.[77] The efficacy trial and postmarketing studies of PCV7 infer that *Streptococcus pneumoniae* is a relatively common cause of pneumonia with patchy or consolidative infiltrates.[82,83] Use of the urine antigen detection test in children with lobar pneumonia also supports the important role of *S. pneumoniae*[84]; however, the test is positive for more than 15% of children with asymptomatic colonization and not recommended for diagnosis.[85]

A Cochrane systematic review of clinical symptoms and signs of *Mycoplasma* pneumonia found the absence of wheezing and presence of chest pain were significant associations.[86] Serologic testing for *M. pneumoniae* using an IgM enzyme immunoassay is problematic because of false-positive test results.[62,87] Detection in throat or nasal specimens using polymerase chain reaction methods is highly sensitive, but the meaning requires clinical interpretation and further study. Ascribing a causal role of pneumonia to *Chlamydophila pneumoniae* is confounded by the findings of prolonged asymptomatic carriage and inconsistent serologic results among studies.[88]

Hemoptysis

Hemoptysis, defined as coughing up blood that originated below the larynx, is uncommon in children. More commonly, blood originates from the upper airway due to epistaxis or other sources. Mechanisms of hemoptysis include bleeding from congenital or acquired abnormal bronchial or pulmonary blood flow, venous obstruction, or vascular abnormalities; immune-mediated endothelial damage; or infectious or traumatic erosion of tracheal, bronchial, or bronchiolar epithelium. Hemorrhage can be mild (e.g., tracheitis, tracheobronchitis) or massive (e.g., congenital malformations, foreign body, bronchiectasis, pulmonary hemosiderosis).

Causes of hemoptysis in children are listed in Table 21.10. Infection is a common cause of hemoptysis, including pneumonia from various causes, including tuberculosis and *Aspergillus*. In a 10-year retrospective study from Texas Children's Hospital, cystic fibrosis patients accounted for 68% of hemoptysis episodes overall.[89]

TABLE 21.10

Causes of Hemoptysis in Children

Epithelial Damage	Vascular Abnormality or Damage
Acute infection (bacterial, fungal, mycobacterial) Bronchiectasis (cystic fibrosis, non–cystic fibrosis, immunodeficiency) Foreign body Trauma (airway or chest, suffocation) Tumor (primary airway or pulmonary, metastatic) Miscellaneous (inhalation medications, factitious)	Congenital heart disease or pulmonary vascular anomalies (venous obstruction, arteriovenous fistula) Congenital malformation (pulmonary sequestration) Autoimmune vasculitis (systemic lupus erythematosus, microscopic polyangiitis, granulomatosis with polyangiitis, inflammatory bowel disease, Goodpasture syndrome, Henoch-Schönlein purpura, Churg-Strauss) Idiopathic pulmonary hemosiderosis Nonspecific endothelial damage (chemical, drug) Coagulopathy Tumors

A chest radiograph, bronchoscopy, coagulation studies, and computed tomography are useful diagnostic modalities in most cases of hemoptysis. If negative, a cardiac evaluation including echocardiography and studies for autoimmune vasculitides may be indicated. Digital subtraction angiography, pulmonary arteriography, or lung biopsy may be indicated.

Abdominal Symptom Complexes

Ishminder Kaur

To guide the clinical approach, abdominal pain usually is classified as acute or chronic/recurrent abdominal pain. Acute abdominal pain demands rapid diagnosis and appropriate intervention so that catastrophic outcomes can be avoided.

Acute Abdominal Pain

Signs and symptoms of medical and surgical conditions that cause acute abdominal pain have considerable overlap. Even though Scholer and associates[1] determined that only 1.1% of 1141 nonscheduled healthcare visits for acute abdominal pain (≤3 days' duration) resulted in a surgical diagnosis, rapid diagnosis and intervention always should be a primary goal to avoid adverse outcomes. In a classic monograph, Cope[2] espoused the first principle of approach to the patient with acute abdominal pain is the necessity of coming to a best, albeit not certain, diagnosis because severe abdominal pain of 6 hours' duration occurring in a previously well child frequently is caused by a condition of surgical importance.

History

The history and character of the patient's acute abdominal pain are elicited with specific consideration of anatomy, embryology, and physiology. Diaphragmatic irritation, for example, causes shoulder pain, because the diaphragm, a high thoracic structure embryologically, shares cervical nerve innervation with the shoulder. A history of therapies already provided is elicited, and potential effects are integrated. Anti-inflammatory agents, especially corticosteroids, can alter expected clinical findings substantially, and potent analgesics or pretreatment with antimicrobial agents can mask otherwise clarifying symptoms. Regimentation in history taking is essential. Three features of pain of particular importance are location, migration, and radiation sites.

Location

Pain over the entire abdomen suggests a diffuse peritoneal process. Pain associated with disease in the small intestine is felt chiefly in the epigastric and umbilical areas, and because innervation of the appendix is similarly derived embryologically, the initial pain of acute appendicitis is located periumbilically. Pain caused by disease in the large intestine usually is felt in the hypogastrium or over the site of colonic abnormality. Pain from pelvic structures also is appreciated in the hypogastrium.

Migration and Radiation

Migration of pain and sites of radiation are useful clues.[3] The early epigastric pain of appendiceal obstruction is carried by visceral pain fibers. After the inflamed appendix irritates or adheres to the abdominal wall, affected somatic pain fibers in the parietal peritoneum cause migration of pain to the right lower quadrant. Similarly, biliary colic begins with epigastric pain but migrates to the right upper quadrant when the inflamed gallbladder contacts the parietal peritoneum. Because the eighth thoracic nerve innervates the bile ducts and infrascapular area of the posterior thorax, pain from biliary colic often is perceived just inferior to the right scapula. Renal and ureteral colic radiates to the ipsilateral testicle. Vertebral pain, as in osteomyelitis, radiates to the corresponding site of abdominal innervation.

Associated Symptoms

The presence, timing, and nature of associated symptoms, especially vomiting, provide important clues to the diagnosis. Pancreatitis can cause severe, repeated vomiting because the inflamed pancreas directly irritates the celiac nerve plexus. Bowel obstruction causes vomiting; the more proximal the obstruction, the more severe the vomiting. High small-bowel obstruction causes intractable bilious emesis early in the course, whereas distal small-bowel obstruction is associated with delayed onset of emesis with long periods between episodes (which can progress to feculent emesis).

Large-bowel obstruction is associated with late-onset emesis or no emesis. Incarcerated inguinal hernia can cause abdominal pain, which manifests as irritability in infants, that is associated with decreased appetite and signs of bowel obstruction. Nausea and loss of appetite can replace vomiting as a symptom in patients with less sensitive triggering of emesis. In children with acute abdominal pain, sudden loss of appetite heightens concern, whereas preserved hunger lessens concern.

Character and Relative Severity of Symptoms

The younger the patient, the less helpful the character of the pain. A sense of well-being between waves of pain is helpful, however. The child with crampy pain from gastroenteritis is playful and active intermittently, whereas children with appendicitis, obstruction, or intussusception do not experience complete relief.

Factors that exacerbate or alleviate pain can be useful clues. The relative importance of symptoms also is helpful. Nausea, vomiting, and diarrhea are cardinal features of gastroenteritis, and abdominal pain is secondary. Abdominal pain is the initial and unremitting feature of acute appendicitis or peritonitis, and other symptoms are less significant.

Physical Examination

A complete physical examination must not be supplanted by imaging studies or laboratory tests.

Vital Signs and Habitus

Vital signs often are normal until the pathologic condition causing abdominal pain is advanced; however, an elevated respiratory rate (out of proportion to temperature) is a clue to thoracic causes of pain that is referred to the abdomen. Abdominal processes that cause splinting of the diaphragm lead to shallow tachypnea and the appearance of a respiratory tract condition. Acidosis related to compromised bowel or infection causes increases in the respiratory rate and tidal volume (i.e., Kussmaul breathing). Abdominal pain associated with emesis, Kussmaul breathing, and dehydration should hasten evaluation for diabetic ketoacidosis. Fever is not a discriminating feature, although high temperatures (≥39.5°C) at the onset of abdominal pain in the absence of vomiting and diarrhea suggest a renal or pulmonary process or primary peritonitis. When abdominal pain and high temperature are associated with vomiting or diarrhea, or both, a primary infectious gastrointestinal cause (e.g., norovirus, *Salmonella*, *Shigella*) is a primary consideration.

The patient's preferred position and degree of movement provide diagnostic information. The child with intussusception lies anxiously, anticipating a paroxysm of pain that causes the child to writhe. The patient with pain due to Henoch-Schönlein purpura (HSP) tosses and turns, trying to find comfort, whereas the child with appendicitis flexes at the waist, and the child with peritonitis lies motionless.

Examination of the Abdomen

Observation of the abdomen may reveal distention, swelling, or a mass. Limited diaphragmatic movement implicates an upper abdominal process, including pancreatic or hepatobiliary disease. Meaningful examination usually requires distraction, warmed hands, and gentle palpation, beginning at the site most distant from the reported location of pain. Palpation can reveal a mass (e.g., intussusception, tubal pregnancy, ovarian cyst, malignancy, hydronephrosis) or a site of tenderness, or it can confirm abdominal rigidity (i.e., sign of parietal peritoneal inflammation). Persistent palpation, as an attempt to overcome localized or generalized abdominal rigidity, elicits greater pain and rigidity unless disease is in the thorax. A rectal examination is necessary and can identify heme-positive stool or mucus, a mass, fullness, or localization of tenderness. It also can prompt consideration of gynecologic conditions.

Percussion of the abdomen usually is not helpful in differentiating abdominal processes. However, dullness suggests the presence of peritoneal fluid and helps delineate edges of the liver or spleen. Auscultation identifies ileus but rarely adds diagnostic specificity.

Other Findings

Additional physical findings of importance seek evidence of respiratory distress (e.g., nasal flaring, retractions, adventitial auscultatory findings), an exanthem (e.g., HSP, gonococcemia), vaginal discharge, pelvic girdle tenderness, and hip pain on testing range of motion. The patient with abdominal pain who holds one hip flexed and externally rotated is likely to have acute appendicitis or primary inflammation of the iliopsoas or obturator internus muscle.

Specific Causes and Approach

Conditions in which acute abdominal pain is the cardinal feature are discussed with a focus on an early clinical approach and intervention. Abdominal pain as part of a syndrome of fever of unknown origin is discussed in Chapter 15. Specific diagnostic studies are discussed elsewhere.

Appendicitis

Acute appendicitis in its classic, most common form can be readily diagnosed before appendiceal rupture in patients who seek attention promptly. Wagner and colleagues[4] described the characteristic sequence of symptoms (rather than any particular symptom) and recognized that the sequence reflects pathophysiologic events (Box 22.1). Interruption of this order should increase suspicion of an alternative diagnosis.

Box 22.1

Expected Sequence of Events or Findings in Appendicitis

1. **Pain, usually epigastric or umbilical**

Appendiceal obstruction and distention stimulate visceral afferent nerves of T8 to T10, referring pain to the epigastrium and periumbilical area.

2. **Anorexia, nausea, and vomiting**

Further obstruction and distention of the appendix lead to colicky pain and reverse peristalsis.

3. **Abdominal tenderness**

Serosal inflammation follows, with irritation of the parietal peritoneum. Pain shifts to somatic fibers, resulting in the localization of tenderness to deep palpation and later localization of pain to the right lower quadrant.

4. **Fever**

Arterial supply of the appendix is compromised, leading to gangrene and rupture. Fever precedes rupture and frank peritonitis and usually is mild (<39°C)

5. **Leukocytosis**

Development of localized peritonitis triggers neutrophilia, which is a relatively late event.

Atypical localization of tenderness and pain can occur, depending on the position of the appendix. If the organ lies retrocecally and cephalad, the serosa abuts the iliopsoas muscle, causing pain that results in a preferred position of flexion at the waist with flexion and external rotation of the right hip. If the appendiceal tip is directed inferiorly, pelvic, left lower quadrant, or urinary symptoms can predominate. Occasionally, pelvic appendicitis can inflame rectal tissue and cause painful defecation, spasms of diarrhea, or rectal obstruction. A mass or tenderness elicited on palpation of the right or anterior rectal wall during rectal examination can clarify the diagnosis. Left-sided appendicitis, sometimes associated with thoracic situs inversus, can cause all of the presentations seen in right-sided appendicitis but in mirror image.

Appendicitis usually evolves from first symptoms to rupture in less than 24 hours.[5] The diagnosis remains a clinical one, although ultrasonography (US) can add specificity, and computed tomography (CT) adds sensitivity and specificity.[6] Clinical scoring systems can help identify children at low risk for appendicitis and potentially avoid radiation exposure.[7] Infants and toddlers present a diagnostic challenge; preoperative ruptures occur in more than 50% of these cases because of patients' inability to communicate classic signs or symptoms and because of lack of distinction from acute gastroenteritis, which is common in this age group.[8]

Mesenteric Lymphadenitis

A diagnosis often made by surgeons during an otherwise normal laparotomy performed for suspected appendicitis is mesenteric lymphadenitis, which has been illuminated with the use of improved imaging techniques. Often larger than 1 cm in diameter, inflamed nodes typically cluster in the mesentery in groups of three or more. The mesentery also can be inflamed and thickened.

Mesenteric adenitis manifests clinically as symptoms of severe, localized abdominal pain that mimics pain of other regional pathologic processes. Unfortunately, diagnoses are not mutually exclusive, and the diagnosis of isolated mesenteric adenitis often is one of exclusion despite visualization of nodes by US or CT.[9,10] An improper sequence of symptoms for acute appendicitis, milder pain, disproportionately high fever, and preserved appetite may permit judicious avoidance of surgery. Mesenteric adenitis can be associated with localized or systemic inflammatory process (e.g., appendicitis, inflammatory bowel disease, acute pancreatitis, cholecystitis, connective tissue diseases), malignancy, and multiple enteric and systemic infections (e.g. *Bartonella* infection, *Yersinia* infection, tuberculosis).[10]

Pneumonia

When abdominal pain is associated with high fever, cough, nasal flaring, tachypnea, respiratory distress, and abnormal auscultatory findings, the diagnosis of pneumonia is obvious. More subtle manifestations make differentiation challenging, but careful attention to degree of fever, initial signs, and meticulous auscultation over all lung fields permits differentiation.

The theory of referred abdominal pain due to diaphragmatic irritation has been refuted by reports of isolated upper and middle lobe pneumonia causing similar pain syndromes.[11] Typical bacterial causes of community-acquired pneumonia are expected.

Pyelonephritis

Specificity of symptoms of urinary tract infection (UTI) is age related. In the neonate and infant, the disease can cause decreased appetite alone or intermittent fussiness. Nonblack race, female sex, lack of circumcision in boys, temperature greater than 39°C, fever of 2 or more days' duration, and absence of another source of infection increase the likelihood of UTI in infants.[12] The toddler often has nonspecific abdominal pain (with or without dysuria). The older child and adolescent are most likely to have dysuria, flank pain, tenderness at the costovertebral angle, and hypogastric pain. Pelvic appendicitis or pelvic abscess from any source can cause dysuria and pyuria, mimicking UTI.

Pancreatitis

The incidence of acute pancreatitis in children is rising.[13] Identifiable causes of pancreatitis vary. Systemic illness, biliary disease, trauma, and medications commonly are identified, but many cases are idiopathic.[14,15] Pancreatitis also is associated with endocrinopathies, autoimmune disorders, multiple organ failure, and metabolic disorders. Alcohol consumption is implicated rarely in pediatric cases.

Anatomic relationships predict the symptoms of acute pancreatitis. The gland lies close to the celiac plexus and semilunar ganglion; consequently, pancreatic inflammation causes nausea, intractable vomiting (never feculent), and severe epigastric pain. The head of the pancreas is surrounded by the duodenum, whereas the body overlies the lumbar vertebrae, and the tail reaches the left flank. Inflammation occasionally causes pain only in the left hypochondrium or flank. Because of the organ's proximity to the diaphragm, pain occasionally can be referred simultaneously to the left scapula and the left supraspinous fossa (i.e., phrenic pain).

Fever of 38.5°C to 39.2°C is common but does not presuppose bacterial superinfection. Epigastric tenderness is expected, but muscular rigidity varies. Jaundice is common and usually is caused by swelling of the head of the pancreas rather than obstructing gallstones.

Hemorrhagic pancreatitis, a life-threatening form of pancreatitis, can have one of two pathognomonic signs: bluish discoloration in the flank (i.e., Grey Turner sign) or around the navel (i.e., Cullen sign). Carbohydrate intolerance can occur as pancreatic islet cells are destroyed.

Acute pancreatitis is a clinical diagnosis supported by elevated serum levels of pancreatic amylase and lipase and abnormal US or CT findings. Edema and parapancreatic fluid collections are typical and should not be overinterpreted as abscess. Serum amylase concentration alone is neither sensitive nor specific. Combined use of amylase and lipase tests increases sensitivity and specificity.[15]

Gallbladder Disease

Acute cholecystitis and infection of the gallbladder rarely are seen in children, except when predisposing conditions exist (e.g., portoenterostomy for biliary atresia, obstructing anomalies). Cholelithiasis, the usual antecedent of cholecystitis in adults, typically occurs without cholecystitis in children. In two pediatric series consisting of 85 patients with gallstones, only 2 patients developed cholecystitis.[16,17] Children with cholelithiasis typically have an identifiable precipitating cause, such as hemolysis, total parenteral nutrition, or adolescent pregnancy. Acalculous cholecystitis (i.e. cholecystitis in the absence of gallstones) is described with increasing frequency among children and often is associated with systemic illness or infectious agents, such as *Salmonella*, Epstein-Barr virus, hepatitis A virus, and others.[18]

The usual sequence of symptoms in patients with cholecystitis is fever followed by colicky epigastric abdominal pain that shifts to the right upper quadrant and then tenderness over the right upper quadrant. An elevated serum concentration of γ-glutamyltranspeptidase and bilirubin (out of proportion to elevation of aminotransferase) is expected. *Enterococcus*, *Escherichia coli,* and other Enterobacteriaceae and oropharyngeal flora occasionally are isolated from blood, hepatic biopsy, or an ascitic fluid specimen.

Biliary dyskinesia is increasingly described in the pediatric literature. In one series of consecutive pediatric patients after cholecystectomy, biliary dyskinesia was implicated in 16% of the patients.[19] Biliary dyskinesia is characterized by functional dysmotility of the gallbladder, causing symptoms mimicking those of cholelithiasis, with right upper quadrant pain and fatty food intolerance. The diagnosis is considered when US fails to identify gallstones despite a high clinical suspicion of gallbladder disease. US may demonstrate gallbladder wall thickening or sludge. The diagnosis is confirmed by a hepatobiliary nuclear imaging scan using cholecystokinin stimulation, but the role of scintigraphy in predicting prognosis or gallbladder pathology in children remains unclear.[20,21] The spectrum of disorders of functional motility can blur the separation of acute and recurrent abdominal pain.

Pelvic Inflammatory Disease

Adolescent women are at higher risk of pelvic inflammatory disease (PID) than adult women. Higher infection rates with *Chlamydia trachomatis* and *Neisseria gonorrhoeae* in general, combined with biologic factors such as immaturity of the menstrual cycle, lack of antibodies to sexually transmitted infectious agents, and extent of cervical ectropion, contribute to the higher risk.[22]

Some women with PID are asymptomatic, and others have only mild or nonspecific symptoms or signs (e.g., abnormal bleeding, dyspareunia, vaginal discharge). Because the manifestations vary widely, PID must be considered with mild lower abdominal pain in a sexually active adolescent. Because of the difficulty of confirming PID and the possible consequence of long-term decreased fertility if it is untreated, a low threshold for diagnosis and treatment of PID is recommended. Diagnostic criteria are listed in Box 22.2.[23]

Box 22.2

Criteria for Clinical Diagnosis of Pelvic Inflammatory Disease

Minimum criteria (if no other cause of illness is identified) include one of the following:

- Uterine/adnexal tenderness

Or

- Tenderness on motion of the cervix

Additional supportive criteria (enhancing specificity of minimum criteria):

- Oral temperature >38.3°C
- Abnormal cervical friability or mucopurulent discharge
- Abundant number of white blood cells on saline microscopy of vaginal secretions
- Elevated erythrocyte sedimentation rate or C-reactive protein
- Laboratory documentation of chlamydial or gonococcal infection

Specific criteria:

- Endometrial biopsy showing endometritis
- Transvaginal sonography or magnetic resonance imaging demonstrating thickened, fluid-filled fallopian tubes with or without free pelvic fluid or tubo-ovarian complex or a Doppler study

suggesting pelvic inflammation (e.g., tubal hyperemia)

- Laparoscopic findings consistent with pelvic inflammatory disease

From Centers for Disease Control and Prevention. Sexually transmitted diseases treatment guidelines, 2015. MMWR Recomm Rep 2015;64(RR-03):1–137.

Classic physical findings are fever, lower abdominal pain or pelvic tenderness (or both), and vaginal discharge. The constellation of abnormal vaginal discharge, a tender mass on bimanual examination, and an elevated erythrocyte sedimentation rate predicts laparoscopically proven PID; however, only 20% of patients with PID have the triad.

Henoch-Schönlein Purpura

In its most common presentation, four features distinguish HSP: purpura due to leukocytoclastic vasculitis, classically palpable and present below the waist (in young children, especially nonambulatory children, distribution can be atypical and often involves the face and scalp); glomerulonephritis, with a spectrum from microscopic hematuria with or without proteinuria to renal failure with severe hypertension; arthritis affecting larger joints and with pain out of proportion to synovial fluid accumulation; and abdominal pain caused by the leukocytoclastic vasculitis. Abdominal pain usually is midline and colicky. Intestinal mucosal purpura causes gastrointestinal bleeding or can initiate intussusception.

Abdominal pain can precede purpura by days (rarely, weeks) in 14% to 36% of patients.[24] Because many patients with HSP have fever and abdominal pain (which can be severe) at onset, intra-abdominal infections and appendicitis often are considered before the typical purpuric rash appears or is seen when the patient is unclothed below the waist.

Enteric and Other Infections

Enteric infections infrequently cause abdominal pain and fever as cardinal features. In the relative absence of gastrointestinal symptoms, however, *Salmonella, Shigella, E. coli* O157:H7, and *Clostridium difficile* infections can cause severe pain due to intestinal spasm before diarrhea; dysenteric stool with mucus and blood clarifies the pathophysiology. *Campylobacter jejuni* infection can mimic inflammatory bowel disease with myalgia and arthralgia associated with bloody stools.

Infections due to *Yersinia enterocolitica* and *Y. pseudotuberculosis* most closely mimic acute appendicitis when they cause mesenteric adenitis. Appendicitis has been associated with numerous pathogens, including cytomegalovirus, *Shigella* spp, *Schistosoma haematobium*, and *Enterobius vermicularis*.[25]

Typhoid fever, visceral abscesses,[26] peritonitis, intestinal granuloma in chronic granulomatous disease, yersiniosis, visceral *Bartonella henselae* infection, cryptococcosis, toxocariasis and brucellosis can manifest as fever with a predominant complaint of abdominal pain. Acute hepatitis can cause abdominal pain, but disproportionate nausea, right upper quadrant tenderness, and hepatomegaly provide clues to the correct diagnosis. Epstein-Barr virus infection can cause predominant abdominal symptoms with severe splenic enlargement.

Streptococcus pyogenes causing acute pharyngitis can cause abdominal symptoms ranging from pain to nausea and vomiting, which are likely related to extracellular enzymes produced by the organism. One prospective study failed to identify abdominal pain as a positive predictor of *S. pyogenes* infection as a singular symptom or combined with other predictive factors.[27] *S. pyogenes* can cause retroperitoneal abscess, necrotizing fasciitis, puerperal sepsis, bacterial peritonitis, and tubo-ovarian abscess, all of which manifest as severe abdominal pain.

Intussusception

Intussusception in childhood is most often idiopathic, with a peak incidence in the United States at 5 to 9 months of age. Typically, infants have no demonstrable intestinal lead point. Hypertrophy of Peyer patches or mesenteric lymphadenopathy may initiate intussusception. Adenovirus has been recovered in stool or mesenteric node cultures in idiopathic cases.[28] Both U.S. rotavirus vaccines are associated with a small (0.19–1.6 events/100,000 doses administered) but measurable excess cases of intussusception in the 3 to 6 days after immunization.[29] Older children are more likely to have a pathologic lead point, identified in 8% of cases,[30] and the most common identifiable cause is a Meckel diverticulum.[31]

Regardless of cause, the clinical manifestations of intussusception are similar. Midline abdominal pain occurs in paroxysms as each peristaltic wave advances the intussusception. An apathetic presentation is seen in approximately 5% of patients; children appear drugged and inattentive rather than writhing in pain. Primary intracranial disease or intoxication can be incorrectly pursued before a palpable abdominal mass or currant jelly stool focuses attention on the intestinal tract. It has been speculated that this peculiar presentation may result from high levels of endogenous opiates released in response to the painful process of intussusception.

Volvulus

Volvulus, which usually occurs in infants with congenital malrotation, is a life-threatening event. Abdominal pain is unusual without associated emesis, which becomes bilious during the acute presentation. Because of vascular compromise, infection is a common secondary event. Although empiric treatment for septicemia is indicated, interrogation for intestinal obstruction should be pursued in the ill infant with bilious emesis.

Occasionally, postprandial pain can be a prominent feature of the subacute or chronic presentation of volvulus. Volvulus can occur in infants with apparently normal intestinal anatomy and in older children. Volvulus and internal hernia with strangulation also should be considered in children with a history of prior abdominal surgery because adhesions can predispose to these events.

Chronic or Recurrent Abdominal Pain

Chronic abdominal pain (CAP) or recurrent abdominal pain (RAP) requires an inclusive, thorough consideration of the medical, psychosocial, and family history. Both CAP and RAP are a subset of functional gastrointestinal disorders. The term *functional abdominal pain* (FAP) is preferred in recent literature. The approach to patients with CAP, RAP, or FAP can involve days to weeks of data collection with only selective use of laboratory tests. Constipation, a common cause of recurrent abdominal pain, is not discussed here.

RAP, as defined by Apley,[32] requires the occurrence of three episodes of pain severe enough to affect activities over a period of 3 months and occurring during the year leading to investigation. Peak incidence of RAP is in 9- and 10-year-old girls. Pain is characterized as paroxysmal, periumbilical, and lasting less than 60 seconds. Its character often is vague but has been described as dull, crampy, or sharp but not temporally related to activity, meals, stress, or bowel habits. The prevalence of RAP among 1000 unselected schoolchildren was as high as 12% among girls.[33] Family histories of children with RAP show a higher incidence of migraine, psychiatric disorders, and peptic ulcer disease than those of controls.[33] In uncontrolled observations from a wide range of practice settings, socioeconomic status correlates directly with the prevalence of RAP.[34]

In 2006, consensus guidelines for the diagnosis of FAP were published from the Rome III group meeting. These guidelines essentially shorten the duration of symptoms, establishing chronicity to 2 months. Symptoms can be episodic or continuous; lack evidence of an inflammatory, anatomic, metabolic, or oncologic process to explain symptoms; and lack criteria for a more specific functional diagnosis.[35]

Differentiating Causes of Recurring Abdominal Pain

FAP disorders are considered more broadly in the biopsychosocial model. While respecting the complex interplay of genetic, psychological variables (e.g., stress, role modeling, intrinsic and extrinsic supports), and physiologic variables (e.g., inflammatory mediators, motility, hyperresponsiveness of environmental stimuli), the clinician must have a pragmatic approach to the individual patient and family. Preferred diagnostic studies are a thorough history, physical examination (between and during episodes of pain), and simple laboratory tests. Extensive use of laboratory testing usually fails to confirm diagnosis and heightens the family's fear and pursuit of missed disease.

Distinguishing features of nonorganic origin are characteristic enough that the clinical diagnosis is not simply a diagnosis of exclusion (Table 22.1). For children who meet Apley criteria for RAP, an organic disease (which if treated, eliminates the symptoms) is identified in less than 10%. In the largest follow-up study of children with RAP, which tracked 161 patients over 5 years, only 3 of the patients were found eventually to have organic disease, which was Crohn disease in all 3 cases.[36]

TABLE 22.1

Features of Nonorganic Versus Organic Causes of Abdominal Pain

Findings	Nonorganic Causes	Organic Causes
Pain location	Periumbilical	Peripheral
Pain character	Dull, crampy	Colicky, penetrating, burning, boring
Pain pattern	Not progressive Follows precipitating event in one third of cases; normal between events; better on weekends	Progressive Associated with meals, or fluid bolus Nocturnal symptoms, daily, persistent
Associated signs	Normal abdominal examination, little objective findings	Retching, writhing Distended abdomen, abdominal tenderness Mouth ulcers, digital clubbing
Associated symptoms	Multiple, vague, often unrelated Headache, dizzy, fatigue Fever absent	Focused, one or two related symptoms, including fever, weight loss, poor growth, arthritis, diarrhea, vomiting, dysuria
Family history	Can be positive for depression, anxiety, migraine	Can be positive for pancreatitis, peptic ulcer, inflammatory bowel disease
Social history	Frequent school absence; high socioeconomic status	—
Screening laboratory tests	Normal ESR, CRP, complete blood count, and urinalysis	Anemia, high ESR and CRP Stool positive for occult blood Abnormal urinalysis

CRP, C-reactive protein; ESR, erythrocyte sedimentation rate.

Nonorganic Causes

The pain of FAP is located centrally, is most often periumbilical, and is vague in character. Associated phenomena such as headache, diarrhea, nausea, pallor, and sleepiness after attacks are common. Fever may occur with the first painful episode, and a few children have recurrent low-grade fever with episodes. Persistent fever or fevers greater than 38.3°C raise suspicion of possible infection or an inflammatory process. Vomiting is common but only rarely occurs with each episode. Recurrent vomiting with painful episodes, particularly if postprandial and associated with bloating, prompts concern for intermittent volvulus. An imaging study performed at the time of an attack may be the only means of clarifying the diagnosis.

Compared with controls, children with RAP are described as fussy, excitable, anxious, timid, or apprehensive. Patients and their parents are described as overly conscientious. The child is indrawn and is more likely to express features of emotional disturbance.[33] With open-ended history taking, precipitating events can be identified at the onset of RAP in one third of cases. In a study of adults by Campo and associates,[37] 28 former RAP patients were significantly more likely than controls to describe anxiety symptoms and disorders, to demonstrate hypochondriacal beliefs, to have greater perceived vulnerability to physical impairment, to exhibit poor social functioning, to be receiving current treatment with psychoactive drugs, and to have a family history of generalized anxiety. In these studies,[33,37] there were trends suggesting associations between childhood RAP and lifetime psychiatric disorder, depression, family history of depression, and migraine. In a cohort of patients referred for CAP, Bakker and colleagues[38] demonstrated an increased auditory startle reflex compared with controls, supporting a theory of generalized hyperresponsiveness to sensory stimuli even outside of the gastrointestinal tract.

Organic Causes

Table 22.2 lists the organic disorders to be considered in the evaluation of patients with RAP. UTI is the most common organic cause. Obstructive uropathy is less common. When pain in the flank and an abdominal mass are identified, abdominal US should be performed; hydronephrosis is most likely. The absence of hematuria and lateralizing pain has been documented in more than one half of the patients younger than 8 years of age who ultimately had urolithiasis as the cause of their RAP; almost 70% had diffuse or central abdominal complaints.[39]

TABLE 22.2

Expanded Diagnosis for Chronic or Recurrent Abdominal Pain

COMMON CAUSES
Psychophysiologic
Recurrent abdominal pain Irritable-bowel syndrome Conversion reaction Task-induced phobia
Gastrointestinal
Nonulcer dyspepsia Gastroesophageal reflux Constipation
Genitourinary
Urinary tract infection
LESS COMMON CAUSES
Genitourinary
Dysmenorrhea Pelvic inflammatory disease Mittelschmerz
Gastrointestinal
Inflammatory bowel disease
RARE CAUSES
Genitourinary
Urolithiasis Tumors (ovarian, renal) Endometriosis Hematocolpos
Gastrointestinal
Angioedema Malrotation Cystic fibrosis Mesenteric cyst Recurrent pancreatitis Cholelithiasis Gallbladder dysmotility Recurrent intussusception Meckel diverticulum Chronic appendicitis Abdominal wall hernia
Neurologic
Intracranial mass Radiculopathy Spinal cord tumor or injury
Cardiovascular
Chronic dysrhythmias Familial dysautonomia Superior mesenteric artery syndrome
Miscellaneous
Abdominal epilepsy Abdominal malignancy Abdominal migraine Acute intermittent porphyria Addison disease Collagen vascular disease Periodic fever syndromes Heavy metal intoxication Hyperthyroidism Wegener granulomatosis

Modified from McGregor RS. Chronic complaints in adolescence. Chest pain, chronic fatigue, headaches, abdominal pain. Adolesc Med 1997;8:15–31.

Gastroesophageal reflux (GER) has been demonstrated in a few studies to be more prominent than previously thought. A study of patients with atypical RAP demonstrated that 56% of consecutively evaluated patients had significant GER as detected by a pH probe; 71% of cases were responsive to histamine receptor type 2 blocking agents and prokinetic agents.[40] Similarly, a Norwegian study prospectively used a pH probe as part of a diagnostic scheme to evaluate children with RAP and demonstrated GER in 21%.[41]

Peptic ulcer disease can cause RAP. A history of recurrent emesis and a pattern of nocturnal pain that awakens the child suggest peptic ulcer disease.[42] *Helicobacter pylori* is the primary cause of peptic ulcer disease in adults[43] and in children.[44] RAP and *H. pylori*[45] have been linked in some selected populations, in which eradication of *H. pylori* was associated with resolution of RAP.[45,46] However, a systematic review of published evidence showed no evidence of association between RAP and *H. pylori*,[47] and *H. pylori* eradication was not associated with symptomatic improvement in patients with RAP in one randomized, controlled trial.[48]

Inflammatory bowel disease can manifest as RAP. Weight loss, poor linear growth, pubertal delay, digital clubbing, perirectal abnormalities (i.e., fistulas or skin tags), joint symptoms, and nocturnal bowel movements raise suspicion of inflammatory bowel disease. Interruption of linear growth can precede overt gastrointestinal symptoms and signs by years.

Abdominal migraine, although rare and challenging to diagnose, is worth addressing because of evidence-based efficacy of treatment with an antimigraine medication. In one small trial of 14 children, pizotifen therapy was associated with fewer days of abdominal pain.[49]

Chronic pancreatitis, although uncommon, can mimic RAP. Measurement of serum amylase and lipase concentrations is justifiable in the evaluation of RAP. Although celiac disease is included as a cause of RAP, the incidence of positive antibodies was no more frequent among children with RAP than age-matched controls in one study.[50] Recurrent episodes of abdominal pain in the setting of periodic fever is one of the differentiating features of familial periodic fever syndromes.

Approach to Diagnosis and Management

As seen in Table 22.1, the clinical features of RAP of nonorganic origin are sufficiently characteristic that the diagnosis often is established after an open-ended history and thorough physical examination. Screening laboratory tests to eliminate more common organic causes (e.g., UTI, inflammatory bowel disease, pancreatitis) can contribute to physician and family confidence in the diagnosis. Screening tests include urinalysis, urine culture, erythrocyte sedimentation rate, C-reactive protein level, complete blood cell count and differential leukocyte count, stool test for occult blood, and serum concentrations of albumin, amylase, and lipase.

Investigation for gastroesophageal reflux may be moving to first-line evaluation. Endoscopy and radiographic evaluation are performed only to evaluate specific leads from the history, physical examination, or screening laboratory test results or if pain is atypical (e.g., right upper quadrant pain and fatty food intolerance, atypical location of pain).

Systematic reviews of multiple treatment regimens for FAP, including RAP, have failed to demonstrate efficacy. Regimens have included dietary fiber supplements, lactose restriction and probiotic supplementation, and pharmacologic interventions.[51,52] Data support the use of psychological therapies, including cognitive-behavioral therapy and hypnosis.[53]

Management of RAP must involve confirmation of the legitimacy of the patient's complaints, expression of empathy for the family's concerns, reduction of the child's stresses and family's unrealistic expectations, resetting of the family's focus on wellness, and normalization of the patient's activities and the family's response to the pain syndrome. Confident reassurance of the patient and family is the treatment for most children with RAP. Assisting the family to gain insight into psychosocial influences on the patient's symptoms is very important. Nonselective use of multiple consultants may be detrimental. Poor outcomes have been associated with the use of more than three consultants.[54]

Neurologic Symptom Complexes

Geoffrey A. Weinberg, Robert Thompson-Stone

The child manifesting symptoms referable to the nervous system is challenging for the clinician and requires a thoughtful approach and evaluation. Often the presence of an infectious disease is not readily apparent. This chapter focuses on the most common presenting neurologic symptoms and features of the history and physical examination that are characteristic of infections, as well as those that distinguish infectious from noninfectious causes. Management, complications, and prognosis are discussed briefly; more details are found in relevant chapters on infectious etiologies.

Headache

Headache occurs in up to 35% to 70% of school-aged children and adolescents.[1–4] Headache is severe enough to be brought to medical attention in a small fraction of cases, although 1% of pediatric emergency department visits are for headaches.[1] Most children evaluated in primary care settings or in a pediatric emergency department with an acute headache and a normal neurologic examination have an acute viral illness, sinusitis, or migraine. Chronic headaches that gradually but progressively worsen in frequency and severity over time are associated with seizures or focal neurologic abnormalities on examination, occur early in the morning or cause awakening at night, or occur in children younger than 3 years are more ominous than acute single or acute recurrent headaches separated by periods of normalcy.[1–4]

History

Important characteristics that aid in differentiating causes of headache are (1) pattern, duration, severity, location, and frequency of pain; (2) associated symptoms, such as fever or purulent rhinorrhea; (3) family history, triggering events, and efficacy of medications; and (4) presence of any underlying condition that predisposes to infection (Table 23.1). Children who have headache coincident with other complaints in which headache is not the cardinal feature rarely have intracranial disease. Although fever is perhaps the most helpful clue in ascribing an infectious origin, its absence does not preclude serious infection. Fever is present in 95% of children with meningitis but in only 30% to 70% of children with a brain abscess.[5,6]

TABLE 23.1

Differentiating Features of Causes of Headaches in Children

				with change of position		
PHYSICAL EXAMINATION						
Altered mental status	++[a]	+	–	+	–[b]	–
Focal deficits	++[a]	++	–	+++	–[b]	+[c]
Nuchal rigidity	+++	++	+	–	–	–

[a] In meningoencephalitis.

[b] Can occur with basilar artery or complicated migraine.

[c] Especially abducens nerve palsy or decreased peripheral visual acuity.

+++, Expected; ++, frequent; +, occasional; –, rare or not associated.

Clues to intracranial disease (in approximate order of importance) include (1) abnormal neurologic examination (especially abnormalities in eye movement or gait); (2) papilledema; (3) headache worsened by cough, Valsalva maneuver, or change in position; (4) forceful vomiting after prolonged period of recumbency; (5) headache that awakens the child from sleep or is most severe on awakening; (6) change in prior headache pattern, especially headache of recent onset with progressive severity and frequency; and perhaps (7) lack of family history of migraine. Questions regarding appetite, activity level, hydration, and mental status also may help identify the seriously ill child.

Physical Examination

Physical examination is directed to exclude life-threatening intracranial disease and begins with evaluation of mental status. Nonspecific terms, such as lethargy and fussiness, should be augmented or replaced by notation of interaction with the environment, consolable irritability, verbalization, and sense of well-being. Specific responses to verbal stimulation should be observed and recorded. If the examiner can elicit a smile from an infant or engage an older child in conversation, acute bacterial meningitis or meningoencephalitis is unlikely, although subacute brain abscesses or tumors are possible.

Meticulous attention to abnormalities in vital signs helps assess the diagnosis, pace of illness, and need for immediate intervention. Examples are tachycardia, hypotension, or orthostatic hypotension in the child with moderate to severe dehydration, toxic or septic shock, or the combination of bradycardia, systolic hypertension (wide pulse pressure), and slow, deep, respirations (Cushing triad) indicating increased intracranial pressure (ICP). Overt signs of impending herniation, such as hyperventilation, Cheyne-Stokes respiration (pattern of progressive increase in depth and sometimes rate of breaths followed by apnea) or ataxic respiration (chaotic gasping and apnea), bulging fontanel, fixed pupils, or anisocoria, must be identified quickly. The presence of papilledema is a specific but insensitive sign of raised ICP. It is rare in children with bacterial meningitis, given the relative rapidity of disease, but is notable in 40% to 70% of children with brain abscess.[5,7] Abnormalities of cranial nerve function, asymmetry in strength, tone, or reflexes, gait changes, and papilledema help define an existing lesion; most children with a brain tumor have some abnormality demonstrable on careful neurologic examination.[1–4]

Nuchal rigidity is present in one fourth of patients with brain abscess[7] and in more than 95% of children beyond the neonatal period with meningitis,[8] but can occur with posterior fossa tumors as well. Fever, headache, and nuchal rigidity can occur with acute bacterial pneumonia, especially that involving the upper lobes; tachypnea is almost invariably present but may have been overlooked.

Sinusitis is a relatively uncommon cause of headache in children (10% to 15%)[1]; data from studies of adults reveal that many “sinus headaches” likely are migraine,[9] but in up to 25% of children with sinusitis, headache is the chief complaint. The constellation of fever, purulent nasal discharge, frontal location of dull pain, and sinus tenderness usually identifies patients with sinusitis.[9] In contrast, children with chronic “sinus headaches” as their only complaint most likely have migraines.

Evaluation

If examination reveals overt signs of increased ICP or focal deficits, brain imaging (computed tomography [CT] or magnetic resonance imaging [MRI]) is warranted urgently as the first study. Electroencephalogram is not recommended in the routine evaluation of headaches in children.[3]

Much discussion has centered on whether a brain imaging study must be performed before lumbar puncture in the child with probable bacterial meningitis to diagnose increased ICP that might induce brain herniation after lumbar puncture.[10] Herniation after lumbar puncture for bacterial meningitis has been reported, but such reports are retrospective in design or anecdotal and often involve a study population including the most critically ill patients, who sometimes have had herniation even without lumbar puncture.[8,10–18] Thus the published incidence of herniation in bacterial meningitis of 4% to 6% is likely biased by both study design and publication bias.[10–12,14,16] It is clear that increased ICP accompanies bacterial meningitis, but in general, the diffusely increased ICP of meningitis, with or without performance of lumbar puncture, is much less likely to lead to brain herniation than the differentially increased (focal) ICP associated with intracranial mass lesions. Unfortunately, even a normal result of brain imaging study does not exclude the uncommon to rare likelihood of herniation.[16,18] A large prospective study of the utility of brain imaging in adults with suspected meningitis showed that imaging is overused and that clinical features alone may suffice to choose which patients can proceed to lumbar puncture without imaging.[19,20] Similar prospective pediatric data are lacking, but several case series show that clinical signs are more accurate than head imaging in prediction of impending herniation in children. In current practice, few children with suspected bacterial meningitis have ICP measured at the time of lumbar puncture; recent data suggest that the normal ranges of pressure are wider than once thought.[10,21]

Thus, in general, if meningitis is suspected in a child without papilledema or focal neurologic findings, a lumbar puncture can be performed without obtaining brain imaging.[8,10,13] Additional important but less common contraindications to lumbar puncture include clinically important cardiorespiratory compromise in a neonate or older child; infection in the skin, soft tissue, or epidural area overlying lumbar puncture site; and severe bleeding diathesis.[8,13]

In the uncommon child with suspected bacterial meningitis and signs of impending herniation or focal neurologic signs, blood cultures are obtained, antibiotics are administered, and an imaging study of the brain is performed urgently. Lumbar puncture is postponed until signs of herniation (as judged by both imaging studies and physical examination) have resolved.

A written and videographic review of lumbar puncture methods is available.[22]

Therapy

Antibiotic therapy for infectious causes of headaches is that which is appropriate for the relevant infection (e.g., sinusitis, meningitis, or brain abscess). In addition, brain abscesses larger than 2.5 cm generally require therapeutic drainage procedures beyond simple diagnostic aspiration.

Altered Mental Status

Diagnostic evaluation of the child with altered mental status focuses on quickly identifying the likely cause or causes and initiating appropriate treatment, which usually is determined empirically. The causes of altered mental status in children are shown in Table 23.2, and differentiating features in Table 23.3. Diagnostic evaluation in the emergency department typically involves rapid testing for hypoglycemia, abnormalities of electrolytes or renal function, and, perhaps, intoxications. The differential diagnosis at the time of infectious diseases consultation usually has been narrowed beyond these noninfectious illnesses.

TABLE 23.2

Causes of Altered Mental Status

Intracranial	Systemic
Infection	**Metabolic encephalopathy**
Meningitis	Endogenous
Viral meningoencephalitis	• Hypoglycemia
Bartonella encephalopathy	▪ Hyperammonemia
Mycoplasma pneumoniae encephalopathy	▪ Hypercarbia
Brain abscess	▪ Hypoxia
Autoimmune, post-para infectious	▪ Uremia
Autoimmune disseminated encephalomyelitis	▪ Hypernatremia or hyponatremia
NMDAR antibodies	▪ Endocrinologic disturbance
CNS vasculitis	▪ Vitamin deficiency (B_{12})
Vascular	Exogenous
Ischemic stroke	• Acute poison ingestion

Primary brain hemorrhage	• Chronic heavy metal exposure
Seizure-related	**Intussusception**
Complex partial status epilepticus	**Hypotension**
Postictal state	**Trauma**
Intracranial mass	

CNS, central nervous system; NMDA, *N*-methyl-D-aspartate receptor.

TABLE 23.3

Differentiating Features of Causes of Altered Mental Status in Children

Feature	**Encephalitis**	**Toxic Ingestion**	**Space-Occupying Lesion**	**Reye Syndrome**
Predominant age	Variable	Toddlers, adolescents	Variable	1–14 yr
Fever	++	+	+	–
Prodrome	Headache, fever, irritability, personality change	–	Headache	Upper respiratory tract infection days before protracted vomiting, stupor, coma
Seizures	++	+	++	–[a]
Focal neurologic signs	++	–	++	–
Other associated findings	Rhinorrhea, rash	Altered pupils or vital signs ↑, ↓ sweating ↑, ↓ saliva		Hepatomegaly

[a] Can occur with markedly increased intracranial pressure.

++, Frequent; +, occasional; –, rare; ↑, increased; ↓, decreased.

Encephalitis or meningoencephalitis in the United States most often is caused by viruses, especially enteroviruses, parechovirus, arboviruses (including St. Louis encephalitis virus, California group encephalitis viruses, eastern equine encephalitis virus, and in the older child and adult, West Nile virus), Epstein-Barr virus, varicella-zoster virus, and herpes simplex virus (HSV, being the one agent clearly treatable with antiviral therapy).[23–28] Bacterial causes of encephalitis or meningoencephalitis include *Bartonella henselae* (cat-scratch disease encephalopathy), *Mycoplasma pneumoniae* (although somewhat controversial because diagnosis has often relied on imperfect immunoglobulin M antibody assays), and rarely, *Listeria monocytogenes*.[13,29–31] Other notable infectious causes of pediatric acute encephalitis or meningoencephalitis of unknown origin include influenza virus, rotavirus, bacteremia, toxic shock syndrome, and rabies (see Chapter 44).

Acute disseminated encephalomyelitis (ADEM) is a presumed postinfectious inflammatory demyelinating illness with acute or subacute onset, which affects multiple areas of the central nervous system (CNS).[32–35] ADEM appears to be more common in children than in adults. Clinical symptoms most often include behavioral changes, alterations in consciousness, and focal neurologic deficits (e.g., limb weakness, ataxia, cranial nerve dysfunction). The cerebrospinal fluid (CSF) protein and white cell count generally are both mildly elevated. Cranial MRI usually reveals large, multifocal, hyperintense lesions on fluid-attenuated inversion recovery or T2-weighted images in the white matter of the brain, but also often affects the thalamus and basal ganglia as well. However, published consensus definitions have emphasized diagnosis based more on clinical changes than on MRI abnormalities[36,37] (see Chapter 45).

Recently, it has become clear that autoimmune-paraneoplastic encephalitides occur more commonly than once thought, and the most common is caused by the presence of autoantibodies to the neuronal cell membrane *N*-methyl-D-aspartate receptor (NMDAR).[38–40] Encephalitis with NMDAR antibodies originally was described to occur primarily in young women with ovarian teratomas, but it is now known that more than 50% of cases of NMDAR encephalitis in children occur in patients without associated tumors. The characteristic illness consists of the acute onset of behavioral and neuropsychiatric changes and seizures, followed by progressive coma, orofacial and upper limb choreoathetoid movement disorder, and dysautonomia. Laboratory findings include CSF lymphocytic pleocytosis (70% to 90% of patients), CSF oligoclonal bands (40% of patients), and abnormal electroencephalogram findings (50% to 100% of patients), yet rather unremarkable MRI of the head (70% to 80% of MRIs normal)—all in association with elevated serum and CSF anti-NMDAR antibodies.[38–40]

History

Important features in the history of altered mental status include age, past medical history, presence of fever, convulsions, symptoms of focal neurologic dysfunction, antecedent illness, immunizations, length and progression of illness, medications in the home, length of time the child or adolescent was unobserved before the change in mental status, and, for adolescents, any recent change in disposition at home or school.

Physical Examination

The degree of alteration in consciousness should be measured specifically. Coma scales, particularly the Glasgow Coma Scale, at times fall short in assessing consciousness in children because the scales require an adult level of neurodevelopment and often have a high degree of interobserver variability.[41] Delineation of the patient's neurologic examination is most useful. Identifying signs of increased ICP or focal neurologic deficit are of utmost importance. A record of normal blood pressure is important and excludes hypertensive encephalopathy.

The remainder of the physical examination focuses on recognition of a toxic syndrome or identification of a systemic illness. Toxic ingestion is supported by abnormalities in vital signs, skin (flushing or sweating), mucous membranes (sparse or excessive saliva), and pupillary size and reactivity. Physical examination of the child with hepatic encephalopathy usually reveals other obvious signs, most notably icterus and decreased liver span, and, in the case of Reye syndrome, hepatomegaly without icterus. Infants with intussusception can come to attention with remarkable lethargy, fluctuating consciousness, or hypotonia instead of, or in addition to, the more familiar features of severe, paroxysmal, colicky abdominal pain and bloody stools, perhaps secondary to release of neuroactive endotoxins or central endorphins.[42] Neuropsychiatric changes and seizures can mark HSV encephalitis or NMDAR encephalitis.

An infectious etiology of altered mental status is likely if there is fever with systemic signs, such as involvement of multiple mucous membranes (e.g., conjunctivitis, mucositis, or pharyngitis), diarrhea, abnormal lung findings, or rash.

Evaluation

Unless steps taken to this point determine a likely extracranial cause of the altered mental status, a brain imaging study is performed to identify focal lesions or evidence of intracranial hypertension and to assess the size of ventricles. MRI is superior to CT in making an earlier diagnosis of HSV encephalitis and in assessing the white matter for changes indicative of ADEM. Lumbar puncture is performed if no mass lesion is identified; opening pressure is measured, and specimens of CSF are sent for multiple tests (see Chapter 44). Not infrequently, these study findings also are normal or show only a mildly elevated CSF protein concentration and mononuclear pleocytosis; the remaining differential diagnosis still may include toxic encephalopathy and encephalitis. Electroencephalography may be helpful in determining a seizure focus and identifying periodic lateralizing epileptiform discharges (a finding that increases the likelihood of but is not pathognomonic for HSV encephalitis) or focal slowing; however, absence of abnormality does not narrow the differential diagnosis significantly. It is noteworthy that complex partial status epilepticus can manifest with only alteration in mental status. Normal values of serum hepatic enzymes and ammonia exclude Reye syndrome (which virtually has disappeared since routine aspirin use in children was halted).[43–45] Close monitoring of neurologic status to recognize the necessity to intervene to manage intracranial hypertension and monitoring of cardiac function for dysrhythmia associated with intoxications are indicated.

Therapy

Infectious causes of altered mental status in which antimicrobial therapy is critical include HSV encephalitis, listeriosis, bacterial meningitis, and brain abscess (along with surgical intervention if large). Empiric therapy for HSV encephalitis is given if no other diagnosis is likely, after appropriate specimens have been collected for culture and molecular identification. Delay in obtaining CSF for polymerase chain reaction testing for HSV does not reduce its sensitivity. Antimicrobial therapy sometimes is given for possible *Bartonella* and *Mycoplasma* encephalopathy or encephalitis, although the effect of antimicrobial therapy in these conditions is unproved.[13] ADEM, NMDAR encephalitis, and CNS vasculitis are treated with anti-inflammatory medications, generally glucocorticoids (along with removal of ovarian tumor if present in NMDAR). Enterovirus and West Nile virus encephalitis are treated with supportive therapy.

Ataxia

Ataxia is a disorder of impaired balance and poor coordination of intentional movement. Ataxia results from cerebellar or brainstem dysfunction due to damage either to the afferent sensory nerve pathways to the cerebellum or to the motor fibers to or from the cerebellum. The differential diagnosis of ataxia in children is broad and includes infectious etiologies primarily when onset is acute or subacute (see Chapters 44 and 132). Before universal childhood immunization against varicella, acute cerebellar ataxia was recognized to be a not infrequent complication of chickenpox. Other uncommon viral causes of acute cerebellar ataxia include Epstein-Barr virus and mumps virus.[32,46] *Listeria* CNS infection sometimes causes rhomboencephalitis (i.e., brainstem encephalitis) with prominent ataxia. Whether postinfectious acute cerebellar ataxia is actually a form of ADEM is uncertain.[32] Differentiating features of acute ataxia are shown in Table 23.4. Benign paroxysmal vertigo of childhood and "basilar migraine" can cause recurrent episodes of acute ataxia with normalcy in between. These entities are considered by most to be migraine-variant conditions.

TABLE 23.4

Differentiating Features of Causes of Acute Ataxia in Children

Feature	Infectious or Postinfectious Cerebellitis	Toxic Ingestion	Neuroblastoma	Basilar Artery Migraine	Benign Paroxysmal Vertigo
Predominant age	<10 yr	Toddler	<5 yr	Any	<4 yr
Fever	– to ++	–	+	–	–
Onset	Acute to subacute	Acute	Subacute	Acute	Acute
Frequency	Single	Single	Single	Recurrent	Recurrent
Duration	Days–weeks	Hours	Months	Minutes–hours	Seconds–minutes
Associated symptoms and signs	Resolving antecedent illness (e.g.,	Altered mental status	Opsoclonus, myoclonus	Disturbed vision; vomiting; headache; vertigo;	Suddenly reaches for support;

	chickenpox)			ataxia; dysarthria	refuses to walk
Results of evaluation	Normal or modest ↑ protein, cells in CSF	Abnormal serum, urine toxin screen	↑ Urine HVA, VMA; abnormal imaging of abdomen and chest		

CSF, cerebrospinal fluid; HVA, homovanillic acid; VMA, vanillylmandelic acid; ++, frequent; +, occasional; –, absent; ↑, increased.

History

History for a patient with ataxia focuses on (1) the child's age; (2) presence of fever, recent illness, immunization, trauma, medications in the home, and ingestion or intoxication; (3) progression, duration, and frequency of the ataxia if intermittent; (4) presence of constitutional symptoms; and (5) family history of migraine headache. Fever and ataxia have only rarely been reported as sole findings in patients with acute bacterial meningitis.[47]

Physical Examination

In considering the differential diagnosis, the clinician should first distinguish cerebellar dysfunction and ataxia from other disorders of gait (e.g., weakness from muscular or neuromuscular disorders, primary hip or limb disease, chorea). The verbal child with middle-ear or inner-ear disease leading to disequilibrium complains of dizziness; this is not usually the case in the child with ataxia due to cerebellar or posterior column disease. The ataxic child generally is not weak, and the Romberg test is positive with eyes both opened and closed. Ataxia due to posterior column disease is associated with a positive Romberg test result only when the eyes are closed.

When disease is localized to the cerebellum, initial evaluation targets life-threatening causes. CNS tumor, particularly brainstem glioma, usually is associated with chronic, intermittent ataxia but rarely can cause acute ataxia. Signs of increased ICP can be but are not invariably present. On the other hand, increased ICP from whatever cause can manifest initially as ataxia.

The general physical examination should be thorough and should be directed at distinguishing etiologies (see Table 23.4). Fever and new or healing rash (e.g., chickenpox) can be clues to acute infectious or postinfectious cerebellitis. Careful examination of skin and scalp for ticks (wood or dog ticks) is warranted because the initial signs of tick paralysis are ataxia and nystagmus; motor weakness and ascending paralysis follow within 48 hours.[48,49] Middle-ear disease can result in vestibular dysfunction and ataxia (with complaints of dizziness and vertigo). The paraneoplastic syndrome of opsoclonus-myoclonus-ataxia occurs in only 2% to 3% of all children with neuroblastoma, but 50% to 80% of children identified with opsoclonus-myoclonus-ataxia are found to have neuroblastoma.[50] Despite a relative increase in survival with treatment of children with neuroblastoma, chronic ataxia and severe neurodevelopmental delay usually persist.[50]

Unless the ataxia is of very short duration, as with basilar artery migraine syndrome and benign paroxysmal vertigo, further evaluation (including cranial imaging, followed by lumbar puncture and perhaps other studies) is necessary, as summarized in Table 23.4 (see also Chapter 45).

Therapy

Empiric therapy with ampicillin for *Listeria* is considered depending on the clinical setting and CSF findings. Postinfectious acute cerebellar ataxia generally resolves spontaneously. Tick paralysis and its initial ataxia are rapidly reversed by removal of attached ticks.

Hypotonia and Weakness

Tone and strength are distinctly different, but intimately related, properties of skeletal muscle. Muscle tone is the least resistance generated against passive movement of the muscle and is best evaluated in the wakeful, relaxed state. Strength is the greatest force that a muscle can generate actively against an opposing force and requires the patient's maximal effort.

Weakness can be associated with both upper motor neuron (i.e., CNS) and lower motor neuron (i.e. peripheral nervous system) diseases. With upper motor neuron conditions (e.g., cerebral palsy or subacute stroke), the weakness is typically accompanied by hypertonia. With a lower motor neuron condition (e.g., spinal muscular atrophy or muscular dystrophy), the child exhibits hypotonia. In infants, CNS disorders can also cause hypotonia without accompanying weakness, and hypotonia is a cardinal feature of disease, whereas weakness is a complaint more often found in the toddler and older child. The spectrum of disease-causing abnormalities in tone and strength varies within these age groups and includes infectious,[26,27,51] postinfectious,[52–55] malignant, and other causes. For these reasons, the features and causes of hypotonia and weakness are considered separately in Tables 23.5 and 23.6.

TABLE 23.5

Differentiating Features of Causes of Hypotonia in Infancy

Feature	**Infant Botulism**	**Myasthenic Syndromes**	**Spinal Muscular Atrophy**	**CNS Injury/Genetic Syndrome**	**Myopathy**
SITE OF DISEASE	Neuromuscular junction	Neuromuscular junction	Anterior horn cell	Central nervous system	Muscle

Musculoskeletal Symptom Complexes

C. Buddy Creech

Musculoskeletal pain is a common presenting complaint in young children and adolescents. The usual cause of musculoskeletal pain is trauma or strain to joint, bone, or muscle. Often, the etiology is never determined and symptoms resolve with symptomatic treatment. The challenge for the clinician is to rule out serious disease, including infection, as a cause of symptoms. This chapter focuses on the illnesses responsible for three different categories of musculoskeletal symptoms—extremity pain, back pain, and chest pain—and the distinguishing features of each of these illnesses.

History

Because the differential diagnosis of musculoskeletal pain is extensive, a comprehensive history must be obtained. Important information includes the acuity of onset of illness and presence or absence of fever. Symptoms that are acute, persistent, and accompanied by fever are more likely to be caused by infection. Chronic or subacute symptoms often are the result of noninfectious illnesses.

Important information obtained in the history of the present illness includes the onset and location, description of the progression and severity of the musculoskeletal pain, and whether pain medication has been used and has been helpful. History is elicited of change in gait, ability to bear weight or move the affected area, joint or soft tissue swelling, and presence of induration, erythema, and warmth. A history of trauma, previous or recent illnesses, growth and development, travel, animal exposures, and medication use is important. A review of systems, including history of fever, skin or mucous membrane lesions, pharyngitis, eye inflammation, lymphadenopathy, respiratory or cardiac symptoms, abdominal pain, vomiting or diarrhea, recent sexually transmitted diseases, or neurologic symptoms, is crucial in determining whether the musculoskeletal abnormalities are associated with systemic disease.

Physical Examination

The primary focus of the physical examination is on pinpointing the location of symptoms in order to generate an accurate differential diagnosis and facilitate diagnostic testing. Examination of infants or young children is difficult because they are unable to verbalize the exact location of discomfort. Because musculoskeletal pain can be due to disease affecting a variety of structures, including joints, bones, muscles, nerves, or blood vessels, careful examination of each of these systems is necessary.

Vital signs document the presence or absence of fever, hypothermia, or cardiovascular instability. Height, weight, head circumference, and general appearance of the child should be noted. Poor growth or weight loss could be consistent with inflammatory bowel disease (IBD) or other chronic inflammatory processes, malignancy, or chronic infections such as tuberculosis. Examination of the eyes may reveal conjunctival hyperemia consistent with Kawasaki disease. Mucous membranes are examined for the presence of ulcers (IBD, Behçet disease, systemic lupus erythematosus [SLE]), an enanthem (group A streptococcal infection, enterovirus infection), or hyperemia (Kawasaki disease). Lymphadenopathy can be seen in juvenile idiopathic arthritis (JIA), malignancy, and Kawasaki disease. The chest is palpated for bone tenderness (malignancy, multifocal osteomyelitis, pleurodynia) and for decreased (pleural effusion) and increased (consolidated lung) tactile fremitus during vocalization; the chest is also percussed for dullness (pleural effusion or consolidation). Auscultation can reveal rales, rhonchi, or wheezing (pneumonia associated with hematogenous dissemination of bacteria to bones, joints, or muscles) or decreased breath sounds such as in pleural effusion (occasionally seen with JIA and SLE). Cardiac examination may reveal a new murmur (endocarditis or acute rheumatic fever [ARF]) or muffled heart sounds (pericarditis). The abdomen should be assessed for tenderness, masses (psoas abscess, tumor), hepatomegaly, or splenomegaly (JIA, malignancy, endocarditis). The skin is evaluated carefully for rash (viral infections, associated bacterial infections or intoxications, Kawasaki disease).

Careful examination of bones, joints, muscles, and nervous system is particularly important. The examiner should note how the patient holds the affected limb and whether areas of skin or soft tissue appear swollen or red. Gait and stance are observed. The bones and muscles in the affected limb should be palpated, and passive and active range of motion of joints evaluated. Pain in the lower extremities can be referred from the back, pelvis, abdomen, or hip. A careful examination of the back and pelvis is necessary to rule out diskitis, vertebral osteomyelitis, pelvic osteomyelitis, or abscess. Bones of the spine and pelvis are palpated, and the spine is assessed for abnormalities in flexion or extension. Skin overlying the vertebral bodies should be examined for the presence of a hemangioma, hair, pit, or mass associated with spinal dysraphism. Infection or structural abnormalities of the hip can cause pain referred to the knee. Examination of the hip joint should be performed in all children with a symptom or sign referable to the lower extremity. Neurologic examination includes evaluation for presence and symmetry of deep tendon reflexes, evaluation for clonus, and sensory examination and estimation of muscle strength. Foot deformities may suggest underlying neurologic conditions.

Laboratory Evaluation and Imaging

The laboratory and radiologic evaluation of patients with musculoskeletal pain is guided by findings on history and physical examination. If infection is suspected, attempts should be made to obtain blood cultures and joint, bone, or tissue culture (depending on location of disease) before initiation of antibiotic therapy.

Synovial fluid cell count and cultures are recommended, particularly for patients with monoarticular arthritis, fever, and no other sites or signs of systemic disease. Inflammatory markers (erythrocyte sedimentation rate [ESR] and C-reactive protein [CRP]) and white blood cell (WBC) counts can be abnormal with infection, inflammatory disease, and hematologic malignancy. Use of other diagnostic tests depends on the differential diagnosis generated on the basis of the history and physical examination.

If a bone or joint disease is suspected, a plain radiograph of the affected area generally is indicated. Both anteroposterior and lateral views should be obtained because abnormalities sometimes can be missed with a single view. Depending on suspected site of the problem, specialized views sometimes are required (Fig. 24.1). Plain radiographs can identify fracture, chronic bone infection, joint effusion, soft tissue swelling, tumor, and structural abnormalities of bone. Ultrasound is useful in identifying joint effusions, particularly in the hip, although a normal ultrasound does not exclude infectious or inflammatory changes in the joint. Magnetic resonance imaging (MRI) or radionuclide scans may be necessary to diagnose bone infections, particularly in the acute phase. These scans also are useful in establishing the diagnosis and extent of bone involvement with malignancies. Radionuclide bone scans are most useful when multifocal disease is suspected.

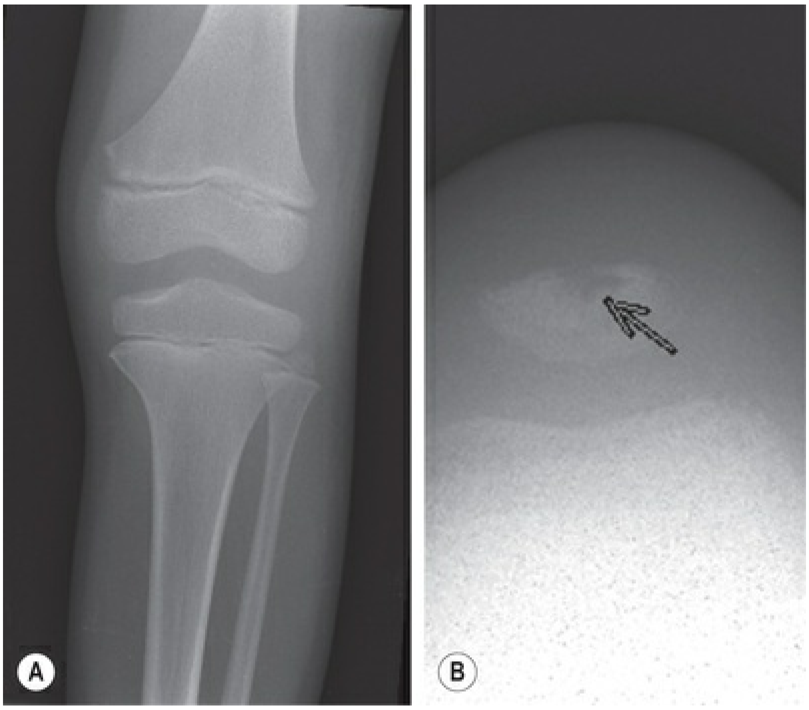

FIGURE 24.1 Radiographs of an 8-year-old boy with fever, limp, and anterior knee pain. Routine posteroanterior view (A) is normal, with lytic lesion of patellar osteomyelitis seen on the sunrise view (B). *Arrow* shows lytic lesion. Limb Pain

The causes of limb pain in children are extensive and include the broad categories of infection, inflammatory disease, malignancy, trauma, and "orthopedic" problems (Box 24.1). These conditions may involve the joints, bones, muscles, or soft tissue of the affected limb.

Box 24.1

Causes of Limb Pain or Limp in Children

Infectious Diseases

Bacterial arthritis

Viral arthritis

Mycoplasma arthritis

Mycobacterial arthritis

Fungal arthritis

Lyme disease

Disseminated *Neisseria gonorrhoeae*

Hepatitis B infection

Subacute bacterial endocarditis

Psoas or obturator internus muscle abscess

Spinal or paraspinal infection

Osteomyelitis

Skin or soft tissue infection

Postinfectious and Reactive Diseases

Acute rheumatic fever

Enteric or sexually transmitted infection

Neisseria meningitidis

Immunization (rubella vaccine, in particular)

Transient (toxic) synovitis

Neoplastic Diseases

Bone or soft tissue tumors

Leukemia or lymphoma

Metastatic neuroblastoma

Hematologic Diseases

Sickle cell anemia

Hemophilia

Rheumatic Diseases

Juvenile idiopathic arthritis

Systemic lupus erythematosus

Spondyloarthropathy

Dermatomyositis

Vasculitis

Henoch-Schönlein purpura

Serum sickness

Kawasaki disease

Orthopedic Conditions

Trauma

Congenital hip dislocation or dysplasia

Slipped capital femoral epiphysis

Legg-Calvé-Perthes disease

Osgood-Schlatter disease

Chondromalacia patellae

Osteochondritis dissecans

Foreign-body synovitis

Physical overuse syndromes

Miscellaneous Conditions

Inflammatory bowel disease

Reflex sympathetic dystrophy

Familial Mediterranean fever

Behçet disease

Sarcoidosis

Neurologic or neuromuscular disease

Fibromyalgia syndrome

Psychogenic disorders

Disease Involving the Joints

Arthritis is a common cause of limb pain in children and can have multiple etiologies (Table 24.1). Infection of the joints can be caused by bacterial and, less often, viral or fungal infection.

TABLE 24.1

Diseases Associated With Joint Pain

Etiology	Joints Involved	Associated Findings	Laboratory Studies	Ancillary Studies
Pyogenic arthritis	Any joint, more often joints of lower extremities, usually monoarticular	Fever, joint pain, redness, swelling, decreased range of motion	Elevated WBC, CRP, ESR. Synovial fluid WBC >50,000/mm^3, predominantly PMN. Blood or joint fluid cultures may be positive	Joint space widening. US shows fluid in joint space
Transient synovitis	Unilateral hip	Recent viral infection, afebrile or low-grade fever, decreased range of motion of hip joint	CBC <12,000/mm^3. ESR <40 mm/hour. CRP <2 mg/dL	US shows fluid in joint space, cannot differentiate infected versus noninfected fluid

Reactive arthritis	Usually large joints of lower extremities, occasionally small joints, wrists, and elbows. Sacroiliac joint involvement in adults	Enteric infection, sexually transmitted diseases, occasionally *Streptococcus pyogenes, Neisseria meningitidis.* Urethritis, mucous membrane ulcers, conjunctivitis may be present	Elevated ESR, CRP. Synovial fluid WBC <50,000 cells/mm^3	HLA-B27 positive
Juvenile idiopathic arthritis				
Systemic	Large or small joints, symmetrically	High fever, evanescent rash, hepatosplenomegaly, lymphadenopathy	Elevated WBC, ESR, and CRP RF and ANAs are negative	
Oligoarthritis	Involvement of ≤4 joints within the first 6 mo of illness	Iridocyclitis can be present.		
Polyarthritis	Involvement of >4 joints within the first 6 mo of illness		Subdivided into RF-positive and RF-negative forms	
Systemic lupus erythematosus	Painful symmetric arthritis involving 2 or more joints, may be migratory	Fever, malar or discoid rash, photosensitivity, oral ulcers, serositis, neurologic abnormalities	Abnormal urinalysis (casts, proteinuria), leukopenia, anemia, thrombocytopenia. Positive anti-DNA or anti-Sm antibody	Radiograph can show pleural effusion ECG can show pericardial effusion
Acute rheumatic fever	Painful, migratory polyarthritis	Fever, carditis, erythema marginatum, chorea, subcutaneous nodules	Elevated ESR, CRP. Evidence of *Streptococcus pyogenes* infection (positive culture, ASO titer, or anti-DNase)	Abnormal ECG

ANA, antinuclear antibody; anti-Sm, anti−smooth muscle; CRP, C-reactive protein; ECG, electrocardiogram; ESR, erythrocyte sedimentation rate; HLA, human leukocyte antigen; PMN, polymorphonuclear cells; RF, rheumatoid factor; US, ultrasound; WBC, white blood cell count.

Pyogenic Arthritis

Pyogenic arthritis usually is the result of hematogenous dissemination of bacteria to the joint space, and less likely the result of direct extension from infected bone, soft tissue, or muscle. The usual bacterial causes vary depending on age (see Chapter 77); *Staphylococcus aureus* is the most common cause of pyogenic arthritis in all age groups. Pathogens typically causing infection in neonates (e.g., group B *Streptococcus* and enteric gram-negative organisms) should be considered in infants younger than 2 months. *Neisseria gonorrhoeae* should be considered in sexually active adolescents. Arthritis caused by *Borrelia burgdorferi* is considered in children who live in or who have traveled to areas where Lyme disease is endemic. Bacterial arthritis can affect any joint, but the joints of the lower extremity are involved most commonly. Pyogenic arthritis typically is monoarticular, but *N. gonorrhoeae* and occasionally *S. aureus* can infect multiple joints. Infants are particularly at risk for infection of multiple joints. Pyogenic arthritis in children is characterized by acute onset of fever, joint pain, redness, and swelling. Physical examination shows markedly decreased range of motion of the affected joint, except in Lyme disease, when effusions characteristically are large and range of motion is relatively preserved.

Pyogenic arthritis of the hip may be difficult to diagnose because associated overlying redness and swelling frequently are not apparent. Pain often is referred to the groin, thigh, or knee. To decrease intracapsular hip joint pressure, the child prefers to hold the affected leg in a flexed, abducted, and externally rotated position. Examination for prone internal rotation is helpful in diagnosing intra-articular hip pathology.[1] The child is placed in a prone position with the pelvis flat on the table and with the knees and ankles flexed and falling away from the body. The examiner tests for pain and limitation of internal rotation. Prompt diagnosis of pyogenic arthritis of the hip is necessary to prevent vascular compromise to the femoral head due to increased intracapsular pressure. Joint effusion can be detected by ultrasonography. If pyogenic hip arthritis is suspected, prompt surgical drainage of infected fluid is indicated.

Transient Synovitis

Transient synovitis is a common cause of limp and hip pain in children 18 months to 12 years of age (mean age, 5 to 6 years) and typically involves a hip joint unilaterally (see Chapter 79). Transient synovitis often occurs in association with a viral respiratory or gastrointestinal illness and may be the result of either direct viral infection of the synovium or a postinfectious response. Although illness is self-limited, resolving with supportive therapy, differentiation from pyogenic arthritis can be challenging. Typically, children with pyogenic arthritis are more likely to have a history of fever, are unable to bear weight, have modestly elevated ESR, CRP, or WBC count, and may have increased hip joint space (>2 mm) on plain radiographs or fluid identified by ultrasonography.[2,3] Because there is overlap in clinical and laboratory findings between transient synovitis and pyogenic arthritis, especially in Lyme disease[4] and *Kingella* infection,[5] careful clinical reassessment is necessary when transient synovitis is suspected.

Other Noninfectious Causes

Reactive arthritis is inflammation of the joint space that occurs in response to an infection elsewhere in the body. Noninfectious inflammatory causes of arthritis generally are more subacute or chronic in presentation. The usual organisms associated with noninfectious reactive arthritis include gastrointestinal pathogens such as *Salmonella* spp., *Campylobacter* spp., *Shigella* spp., *Yersinia* spp., *Clostridium difficile,* sexually transmitted infections such as *Chlamydia trachomatis* and *N. gonorrhoeae,* and occasionally *Streptococcus pyogenes*.

JIA is considered in children younger than 16 years when symptoms of joint inflammation have been present for 6 weeks or more and other causes have been excluded.[4] Categories of JIA include systemic arthritis, oligoarthritis, and polyarthritis.[5] Systemic JIA typically manifests with high fever, an evanescent rash, hepatosplenomegaly, generalized lymphadenopathy, and occasionally pleuritis and pericarditis. These symptoms can precede joint involvement by several weeks to months. Symmetric involvement of large or small joints is typical. The WBC, ESR, and CRP usually are elevated. Rheumatoid factor and antinuclear antibodies usually are not present. Oligoarthritis is characterized by involvement of 1 to 4 joints within the first 6 months of disease, often in association with iridocyclitis. Polyarthritis is inflammation of 5 or more joints during the first 6 months of illness and is further divided into rheumatoid factor–negative and rheumatoid factor –positive forms. SLE is a multisystem autoimmune disease often associated with arthralgia and arthritis. Although children of any age can develop SLE, it most commonly develops in females around the time of puberty or during pregnancy. Children and adolescents can come to medical attention with constitutional symptoms of fatigue, weight loss, hair loss, lymphadenopathy, and hepatosplenomegaly. Nonerosive painful and symmetric arthritis involving two or more joints are seen commonly. Criteria for diagnosis of SLE include the presence of at least 4 of 11 findings: malar rash, discoid rash, photosensitivity, oral ulcers, arthritis, serositis (pleural or pericardial effusion), renal dysfunction (proteinuria or cellular casts), neurologic derangement, hematologic disorder (anemia, leukopenia, lymphopenia, or thrombocytopenia), presence of anti-DNA antibody or anti–smooth muscle antibody, and presence of antinuclear antibody.[6,7]

ARF is a nonsuppurative complication of *S. pyogenes* infection.[8,9] Diagnosis is based on clinical and laboratory findings. Exquisitely painful migratory polyarthritis typically involving the elbows, knees, and ankles is a major criterion for diagnosis of ARF. Arthritis occurs early in the course of illness and does not result in chronic joint disease. Other major criteria of ARF include carditis, erythema marginatum, chorea, and subcutaneous nodules. Minor criteria of ARF include fever, arthralgia, elevated ESR or CRP, and prolonged PR interval on electrocardiogram. Two major criteria of ARF or one major and two minor criteria plus laboratory evidence of a preceding *S. pyogenes* infection are necessary to establish the diagnosis of ARF. Chorea alone can be used to diagnose ARF if other causes have been excluded.

Hip and knee pain also can be the result of noninfectious and noninflammatory structural abnormalities. Hip pain in boys 2 to 12 years old (mean, 7 years) can be secondary to Legg-Calvé-Perthes (LCP) disease. LCP disease occurs when blood supply to the proximal femoral epiphysis is disrupted, resulting in necrosis and infarction of the femoral epiphysis. Predisposing factors are not completely known, but cardiolipin antibodies and thrombophilic coagulation disorders increase the risk for LCP.[10] The most common clinical complaint is limp or vague chronic pain in the groin or anterior thigh. Findings include antalgic gait (shortened stance and prolonged swing phase), muscle spasm, and mild limitation range of motion of the hip. Diagnosis is made by plain radiographs of the hip and pelvis.

Slipped capital femoral epiphysis (SCFE) also must be considered as a cause of hip and knee pain.[11] SCFE occurs when there is displacement of the proximal femoral head anterolaterally and superiorly. Sometimes there is a history of associated trauma or chronic pain. Pain often is referred to the anterior thigh or knee. Affected adolescents often are obese, but SCFE can occur in children of normal weight. Both hips are involved in a substantial number of cases. Physical signs of an acute slip include severe pain when range of motion is attempted. A child with a chronic stable SCFE complains of vague intermittent dull aching pain involving the hip and groin over a period of several weeks. Diagnosis is made by plain radiographs of the hips and pelvis.

Knee pain can be caused by a variety of processes, including Osgood-Schlatter disease, patellofemoral pain syndrome, and osteochondritis dissecans. Osgood-Schlatter disease is an inflammatory disorder of the proximal tibial physis in which the patellar tendon inserts on the tibia. Pain is most pronounced over the tibial tubercle. Osteochondritis dissecans of the knee occurs when an area of bone adjacent to cartilage separates. The cause is unclear but may be related to repetitive trauma.[12] Children complain of nonspecific aching knee pain exacerbated by exercise. Tenderness of the anterior medial aspect of the knee can be noted. Plain radiography shows lesions most often in the medial distal femoral condyle. Patellofemoral knee syndrome is one of the most common causes of knee pain. Pain may be the result of trauma to the patella or peripatellar tissues, overuse, or abnormal patellar tracking. Risk factors include quadriceps weakness and tightness of patellar soft tissue.[13] Symptoms include dull aching pain during activity and with prolonged sitting, joint stiffness, and crepitus. Diagnosis is based on physical examination.

Other causes of joint pain in children include hematologic malignancies and trauma.

Diseases Involving Bone

Infectious Causes

Osteomyelitis is an important cause of limb pain in children (see Chapter 76). Osteomyelitis in children generally is caused by hematogenous dissemination of bacteria to the bony metaphysis. Infection usually is well localized. Multifocal bone involvement sometimes is reported in infants. Most cases of osteomyelitis involve the long bones; however, a substantial number of infections involve bones in the pelvis. Pelvic osteomyelitis can be difficult to diagnose because pain often is poorly localized and may be referred to the hip, groin, or buttock.[14] Onset of fever and bone pain generally is acute, although in some cases fever can be low grade, with intermittent bone pain evolving over a few weeks. Children can come to medical attention with limp or extremity pain. Physical examination can reveal tenderness, redness, warmth, and swelling over the affected bone. Children with pelvic osteomyelitis have pain on compression of the bones of the pelvis. A draining fistula can occur in patients with chronic osteomyelitis. Plain radiographs in acute osteomyelitis show deep soft tissue swelling within a few days after onset of symptoms. Changes consistent with bone destruction typically are not visible for 2 or 3 weeks after onset of symptoms. Bone scan or MRI is useful for early diagnosis of osteomyelitis. WBC, CRP, and ESR frequently are elevated and blood cultures frequently are positive.

Noninfectious Causes

Noninfectious causes of bone pain include trauma, stress fracture, “growing pains,” malignancy, and hemoglobinopathies. Trauma generally is diagnosed by history. “Growing pains,” the cause of which is poorly understood, are characterized by bilateral leg pain typically occurring at night, with no symptoms during the day. Malignant tumors associated with bone pain include osteosarcoma, Ewing sarcoma, and hematologic malignancies such as lymphoma and leukemia.[15,16] Night pain severe enough to awaken a child from sleep, diffuse or migratory bone pain, and pain out of proportion to findings on physical examination raise concern for a malignant process. Vaso-occlusive crises in patients with sickle cell disease manifest with fever and bone pain and can be difficult to differentiate from osteomyelitis. Rarely, chronic recurrent multifocal osteomyelitis (CRMO) can be a cause of limb pain. CRMO is characterized by periodic episodes of fever and bone pain, often involving the jaw, clavicle, and calcaneus. CRMO can be associated with febrile neutrophilic dermatosis and pustulosis palmaris or plantaris.[17]

Muscle Diseases

Infectious Causes

Pyomyositis is a bacterial infection of skeletal muscle that can cause limb pain, particularly in the lower extremities.[18,19] Muscle infection probably occurs when hematogenous bacteria are seeded to injured muscle. The most common bacterial causes of pyomyositis are *S. aureus* and *S. pyogenes*, although a number of gram-negative and anaerobic organisms also can infect muscle. Presentation can be subacute, and symptoms include fever, pain, swelling of the affected extremity, and limp if the lower extremity is involved. Initial symptoms of pyomyositis include malaise and cramping muscle pain. The overlying skin can appear normal; the muscle involved feels firm on palpation. As the infection progresses, abscesses form in the muscle, and the affected area becomes tender, red, and swollen. Untreated, pyomyositis can progress to septicemia, shock, and, rarely, death. The WBC, ESR, and CRP generally are elevated. The causative bacteria are usually isolated from abscess culture; blood cultures also can be positive. Persistent bloodstream infection can occur, especially with *S. aureus*. Ultrasound, computed tomography (CT), and MRI can be used to diagnose and determine the extent of infection. The differential diagnosis of pyomyositis includes cellulitis, fasciitis, osteomyelitis, pyogenic arthritis, thrombophlebitis or deep vein thrombosis (which can coexist with pyomyositis), muscle strain, malignancy, or compartment syndrome.

Viral infection of muscles also can cause inflammation and severe pain. Viruses most commonly reported include influenza (particularly influenza B), enteroviruses, and human immunodeficiency virus. Myositis associated with influenza infection manifests as acute pain and tenderness of the gastrocnemius and soleus muscles, making it difficult for the patient to walk.[20,21] On physical examination, localized tenderness and swelling of calf muscles are noted. Serum creatinine kinase levels are elevated. Rhabdomyolysis occurs in rare circumstances and is more common in girls and after influenza A infection.

Parasitic causes of myositis include *Trichinella* spp., *Taenia solium* (cysticercosis), and *Toxoplasma gondii*[22] (see Chapter 75).

Noninfectious Causes

Noninfectious illnesses that are associated with muscle inflammation generally present less acutely than infections of muscles. Dermatomyositis is nonsuppurative inflammation of striated muscle and is the most frequently diagnosed inflammatory myopathy in children.[23,24] Onset of illness is insidious, and symmetric weakness of proximal muscle groups, rather than pain, usually is the presenting symptom. The illness is associated with a characteristic malar rash and blue purple discoloration of the upper eyelids. The skin over extensor surfaces of joints can be scaly and erythematous. Affected muscles often are stiff and tender to palpation. Associated clinical findings include joint contractures, dysphagia, and cardiac arrhythmias. Serum creatinine kinase levels are elevated. Diagnosis is confirmed by electromyography; muscle biopsy typically reveals perivascular inflammation.

Fibromyalgia syndrome is a chronic pain syndrome characterized by chronic musculoskeletal pain in the absence of any other underlying medical condition or elevation of serum inflammatory markers.[25] Criteria for diagnosing fibromyalgia syndrome are not well defined in children or adolescents. In adults, symptoms include diffuse musculoskeletal pain in at least three areas of the body for at least 3 months, accompanied by pain over at least 11 of 18 previously defined trigger points. Associated symptoms include nonrestorative sleep, fatigue, chronic anxiety, chronic headache, the feeling of soft tissue swelling, irritable bowel syndrome, extremity numbness, and modulation of pain by stress, weather, or physical activity.

Diseases of Soft Tissue and Fascia

Limb pain can be the result of cellulitis or infections involving the deeper levels of the dermis and superficial muscle fascia. The most serious of these infections is necrotizing fasciitis.[26–29] Necrotizing fasciitis is a bacterial infection that spreads rapidly along fascial planes, causing necrosis, thrombosis, and extensive tissue damage. Bacterial causes of necrotizing fasciitis include methicillin-susceptible and methicillin-resistant *S. aureus, S. pyogenes,* gram-negative bacteria, and anaerobic organisms, including *Clostridium* spp. and *Bacteroides* spp. Infection can be polymicrobial.

Predisposing factors include trauma, burns, omphalitis, varicella infection, and immunosuppression. Most patients with *S. aureus* or *S. pyogenes* previously were healthy. Symptoms are rapid in onset, and the patient often appears to have pain out of proportion to findings on physical examination. The patient can have high fever and tachycardia and appear very uncomfortable. Blisters or bullae can be present over the affected area, skin can appear dusky, and the underlying tissue is exquisitely tender. Crepitus is present in some cases. Untreated, infection spreads rapidly, progressing to hypotension, shock, and multisystem organ failure. Diagnosis requires a high index of suspicion. WBC count higher than 15,000 cells/mm^3 and serum sodium concentration less than 135 mmol/L may help distinguish necrotizing fasciitis from cellulitis.[30] One group of investigators has developed a laboratory scoring system of risk indicators for necrotizing fasciitis using CRP, WBC, hemoglobin, serum sodium levels, serum creatinine, and glucose to estimate risk for necrotizing fasciitis.[31] This scoring system has not yet been adequately validated in prospective studies and should not be used to exclude necrotizing fasciitis in a patient. MRI is the preferred imaging modality for ascertaining involvement of the fascia. CT is somewhat less sensitive but may be more readily available, facilitating expeditious evaluation of a critically ill patient.[28] Biopsy of the affected area is useful in determining depth of infection. Management of necrotizing fasciitis involves surgical debridement, empiric broad-spectrum antibiotics, and supportive care in an intensive care unit. The differential diagnosis includes pyomyositis and cellulitis.

Back Pain

Back pain is a common complaint in children, particularly in adolescents,[32,33] and can have multiple etiologies, including uncommon but serious problems such as primary infection or tumor (Box 24.2). Infection can be present in the disk space, vertebral body, epidural space, or a paravertebral or psoas muscle (Table 24.2). Upper-back or neck pain can be associated with meningitis, retropharyngeal abscess, or Ludwig angina.

Diseases Associated With Back Pain

	Clinical Features	Clinical Findings	Laboratory Studies	Ancillary Studies
Diskitis	Children <6 yr. Subacute presentation. Nonspecific signs: refusal to walk, difficulty sitting, abdominal pain	Low-grade fever, limp, pain with hip flexion, loss of normal spine lordosis	Elevated ESR and CRP. Blood cultures or disk space cultures are rarely positive	After 2–4 wk, plain radiographs show narrowing of disk space and irregularity of vertebral end plate
Vertebral osteomyelitis	Older children. Signs can be subacute	Fever, pain in back, chest, abdomen; tenderness over involved vertebral body variable, paraspinous muscle spasm variable; loss of normal spine curvature; neurologic deficits in 15%–20%	Elevated ESR and CRP. Blood cultures positive in 30%	Plain radiographs show narrowing of affected disk space and lucency of the affected vertebral bodies on either/both sides. MRI delineates extent of disease
Spinal epidural abscess	Anterior abscess results from spread of vertebral body or disk space infection. Posterior abscess results from hematogenous source. History can include surgery to spine, trauma, immune dysfunction, congenital anomaly of spine	Fever, back pain, malaise, limp; as infection progresses: radicular nerve pain, muscle weakness, bowel and bladder dysfunction; soft tissue swelling over back	Elevated WBC, ESR and CRP. Blood and abscess cultures positive	MRI delineates extent of abscess, bone, or muscle involvement
Psoas muscle abscess	Primary abscess results from hematogenous source. Secondary abscess results from underlying bowel pathology	Fever, abdominal pain, hip pain, limp, and back pain; psoas sign; if abscess is large, a mass may be palpated in the	Elevated WBC, ESR, and CRP	Abdominal US or CT can confirm the diagnosis

		abdomen		

CRP, C-reactive protein; CT, computed tomography; ESR, erythrocyte sedimentation rate; MRI, magnetic resonance imaging; US, ultrasound; WBC, white blood cell count.

Infectious Causes

Diskitis

Diskitis is inflammation of the intervertebral disk and the vertebral body end plates (see Chapter 78). Children younger than 6 years are affected most often.[34] The rich vascular anastomosis between vertebral bodies in the young child may account for the higher incidence of inflammation localized to the disk space and vertebral end plates, with relative sparing of vertebral body. Infection and destruction of the vertebral body are more frequent in older patients. Diskitis usually involves the lower thoracic or lumbar spine. Cultures for bacteria usually are negative. *S. aureus* is most frequently isolated when cultures are positive. Other bacteria that have been isolated occasionally from blood or disk space cultures include *Kingella kingae,* enteric gram-negative bacteria, and *S. pneumoniae*. Clinical findings in children with diskitis vary depending on age. Symptoms are subacute and increase in severity over several days. The young child is likely to manifest nonspecific signs of irritability or refusal to walk.[35] Older children may localize pain to their back or complain of abdominal symptoms, leg pain, or hip pain. On physical examination, the child may refuse to walk or walk with a limp. Hip flexion causes pain. Loss of normal lordosis of the spine is typical. Plain radiographs of the back are normal initially, but after approximately 2 to 4 weeks, narrowing of the affected disk and irregularity of the vertebral end plates are observed. ESR and CRP usually are elevated modestly.

Vertebral Osteomyelitis

Infection of the vertebral bodies is relatively rare in children compared with adults.[36] Infection is the result of hematogenous seeding or spread from contiguous infection of muscle, soft tissue, or the gut.[37] *S. aureus* is isolated most commonly, although infections with gram-negative enteric bacteria are reported. If the process appears chronic, infection with *Mycobacterium tuberculosis* should be considered. Children with vertebral osteomyelitis generally have fever but can come to attention primarily for back pain (Fig. 24.2). Pain can be localized to the affected area of the back or referred to the chest, abdomen, and legs. Spasm of paraspinous muscles often is present, as is loss of normal curvature of the spine. The neurologic examination is abnormal in some cases. Blood culture is positive in 30% of cases, and WBC, ESR, and CRP often are elevated. Plain radiographs or MRI shows involvement of the disk space and also destruction of adjacent vertebral bodies. If the blood culture is negative, biopsy of the affected vertebral body should be considered.

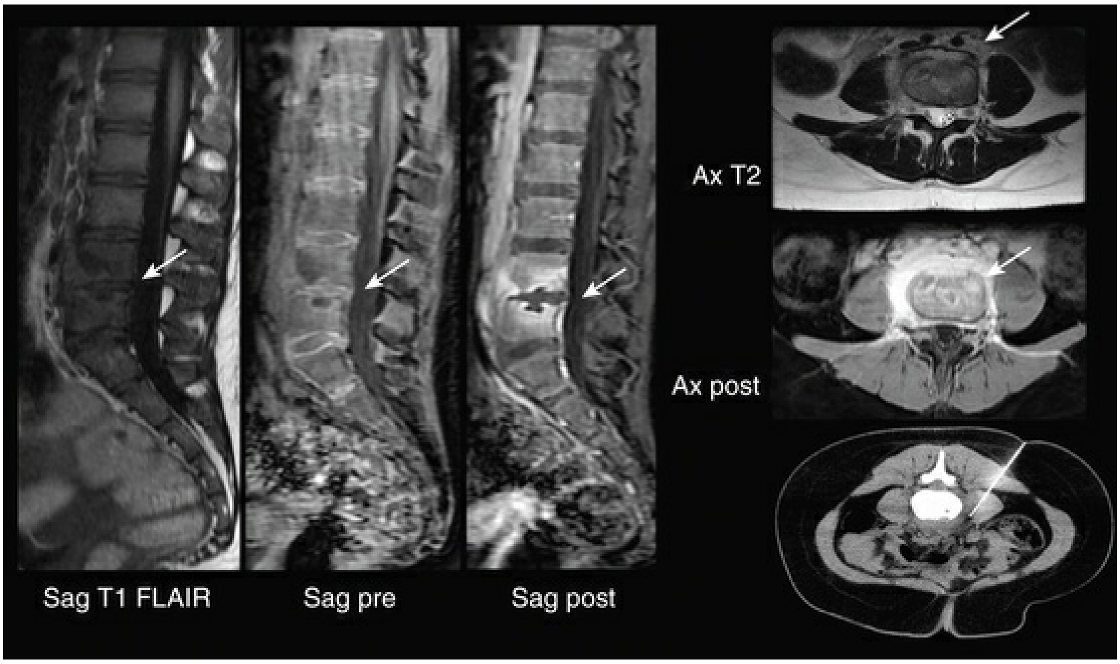

FIGURE 24.2 Magnetic resonance imaging (MRI) in a 12-year-old girl with progressive lower back pain over 4 weeks, which began 4 weeks after returning from the Dominican Republic where she had a 5-day febrile illness. She was afebrile at presentation and had pain only when standing, which was worse on bending forward. There was no tenderness over her spine; C-reactive protein was mg/dL, and erythrocyte sedimentation rate was 62 mm/hour. Vertebral osteomyelitis and anterior paraspinal abscess were best seen on postcontrast sagittal and corresponding axial MRI. Biopsy at the site shown revealed *Salmonella* serotype Typhi. (Case and images courtesy of Long SS and Faerber EN, St. Christopher's Hospital for Children, Philadelphia, PA.)

Spinal Epidural Abscess

Spinal epidural abscess is a rare but potentially catastrophic infection in children.[38] Most epidural abscesses are located posteriorly in the thoracic and lumbar spine and result from hematogenous seeding.[39] Anterior epidural spinal abscesses can result from extension of infection from a vertebral body or disk space, or from the retropharyngeal or retroperitoneal space. Predisposing factors include trauma, previous spinal surgery, and immunodeficiency. Epidural abscesses have been reported in young children with congenital abnormalities such as a neuroenteric fistula[40] or Currarino triad (congenital sacral abnormality, anorectal malformation, and a presacral mass).[41] *S. aureus* is most often isolated, but other gram-positive, gram-negative, and anaerobic organisms have been identified from culture of abscess material.

Initial clinical findings include back pain, malaise, fever, and difficulty walking. As the abscess increases in size, sensory and motor abnormalities typically appear. Untreated, radicular nerve pain, muscle weakness, and bladder or bowel dysfunction can develop. Local tenderness may be noted and, in young children, soft tissue swelling over the lower back may be observed. Blood cultures are positive in 60% of cases, and the WBC count usually is elevated. Diagnosis is made by gadolinium-enhanced MRI. Patients should be managed with a pediatric neurosurgeon because urgent surgical decompression usually is necessary to prevent neurologic sequelae.

Muscle Abscess

Psoas muscle abscess can cause back pain, limp, hip pain, or abdominal pain.[42,43] Psoas muscle abscess is classified as primary or secondary. Primary abscess is more common in children compared with adults and occurs without an obvious intra-abdominal focus of infection. Most primary psoas muscle abscesses are caused by *S. aureus,* although older reports emphasize the importance of *M. tuberculosis.* Secondary psoas abscesses arise as a complication of gastrointestinal conditions (e.g., appendicitis or IBD) or pelvic, renal, or urologic infection. Inflammation of the psoas muscle can result in pain elicited on extension of the thigh (“psoas sign”). This sign is not present consistently, particularly in the young, frightened, irritable child.[42] If the abscess is large, an abdominal mass can be palpable. Inflammatory markers and WBC count generally are elevated. Diagnosis can by confirmed by ultrasound or CT.

Noninfectious Causes

Spondylosis is a defect in the lamina of the vertebra between the posterior articular facets, usually at L4 or L5.[44,45] This defect may occur as a result of trauma or genetic predisposition. When the defect is bilateral, the vertebral body can slip forward (spondylolisthesis). Patients complain of lower back pain and leg pain. Lumbar flexion and extension are limited, and hyperextension of the lumbar spine exacerbates pain. Muscle spasm of the hamstring and paravertebral muscles can be present. Standing lateral and supine oblique radiographs of the lower back are diagnostic.[45]

Scheuermann kyphosis manifests in late childhood and is hypothesized to result from defects in ossification of the anterior portion of the vertebral body or vertebral body wedging due to abnormal biomechanical stress.[46] Progressive wedging of the vertebral body produces kyphosis. Back pain is more common in adults than in adolescents. On physical examination an angular deformity of the back is noted when the patient bends forward. With postural kyphosis, the back deformity is more rounded and less angular. Diagnosis is made by anteroposterior and lateral radiographs of the back.

Children with malignant spinal cord tumors present with back pain that typically is worse at night,[33,35] abnormal gait, and scoliosis. Tumors are classified by location. Intramedullary tumors generally are located in the cervical region of the spinal cord. Lymphoma, neuroblastoma, and sarcomas can metastasize to extramedullary sites, in either intradural or extradural locations. Neurologic abnormalities, including muscle weakness and sensory deficits, commonly are seen.[35,47] Deep tendon reflexes can be diminished at the level of tumor infiltration and increased below the level of the lesion. Bowel and bladder function can be impaired. Although plain radiographs show vertebral body destruction, MRI generally is used for diagnosis.

Chest Pain

Most children who present with chest pain either have a musculoskeletal cause of pain or the etiology is never determined (Box 24.3).[48–50] Musculoskeletal symptoms often are a result of trauma or strain. Infection involving the muscles or bones of the chest wall, lungs, heart, or mediastinum can cause chest pain. Less common causes of chest pain include pulmonary disease, gastrointestinal disease, and, in fewer than 10% of cases, cardiac disease (Table 24.3).

TABLE 24.3

Diseases Associated With Chest Pain

	Clinical Features	Clinical Findings	Laboratory Studies	Laboratory Studies
Osteomyelitis	Infection of the ribs or sternum uncommon; can result from contiguous infection from lungs (fungal or actinomycoses), or previous surgery or trauma	Fever, tenderness, erythema, and warmth over affected bone, sinus tract, or poorly healing surgical site	Elevated WBC, ESR, CRP. Blood or tissue cultures can be positive	Plain radiographs show bone destruction. Bone scan can be useful if multifocal disease suspected
Pleurodynia	Acute onset of sharp chest or upper abdominal pain. Preceding respiratory or enteric illness	Fever, pain worse on inspiration, mild chest wall tenderness	Enterovirus can be identified in respiratory secretions or stool	
Costochondritis	Acute or subacute onset of anterior chest wall pain	Tenderness over the costochondral or costosternal junctions (usually 2nd to 5th costal cartilages); unilateral	Elevated ESR in some patients	Radiograph normal; occasionally soft tissue swelling at costochondral junction or cartilage calcification
Pneumonia	Acute onset. Preceding URI, cough	Fever, hypoxia, tachypnea, decreased breath sounds, dullness to percussion, rales, rhonchi	Elevated WBC, ESR, CRP. Blood and sputum cultures can be positive	Radiograph abnormal
Pulmonary embolus	Risk factors include the presence of a central venous catheter,	Tachypnea, tachycardia, rales, loud S_2	Positive D-dimers	Radiograph nonspecifically abnormal

	immobility (and other, discussed in text). Acute onset of dyspnea, pleuritic chest pain, cough	and S_4		
Pericarditis	Precordial pain, can be referred to neck or arm	Fever, distant heart sounds, pericardial friction rub; relief of pain if patient bends forward		ST segment elevation, PR segment depression, T wave changes, low voltage with effusion. Radiograph can show increased heart size
Myocardial infarction	Rare in children, usually underlying anatomic heart disease or acquired heart disease (Kawasaki disease)	Hypotension, shortness of breath, cyanosis, anxiety	Elevated cardiac enzymes (reliability in children not well evaluated)	ECG changes: arrhythmias, ST segment changes, wide Q waves
Aortic dissection	Patient may have clinical features of Marfan disease. Acute onset of pain that can radiate to the back	Tachycardia, soft murmur over the aorta, hypotension	Echocardiogram confirms diagnosis	

CRP, C-reactive protein; ECG, electrocardiogram; ESR, erythrocyte sedimentation rate; URI, upper respiratory tract infection; WBC, white blood cell count.

Bony and Cartilaginous Causes

Osteomyelitis of the ribs or sternum is uncommon but causes chest pain. Extension of infection from the lung with organisms such as *Aspergillus* spp. *or Actinomyces* spp. occasionally can cause infection of the contiguous bones and soft tissue.

Bacterial pyomyositis and necrotizing fasciitis occasionally involve muscle and fascial tissue of the chest wall.

Enterovirus infection (usually coxsackieviruses or echoviruses) can cause inflammation of the intercostal muscles, upper abdominal muscles, and pleura. The patient often has nonspecific symptoms of a viral illness, fever, and acute onset of sharp chest or abdominal pain. Pain is worse with inspiration and cough. Diagnosis is made by identifying virus in respiratory secretions.[51,52]

Costochondritis is an inflammatory process involving the costochondral or costosternal joints. Rarely, biopsy and culture of cartilage reveal a bacterial pathogen. Patients manifest anterior chest wall pain and tenderness over the costochondral junction of affected ribs. In contrast to Tietze syndrome (described later), swelling, erythema, and warmth generally are not noted. The sedimentation rate can be elevated. Plain radiographs are normal or show soft tissue swelling, and occasionally cartilage calcification and destruction.

Tietze syndrome is distinguished from costochondritis by the presence of swelling in the area of pain.[53] It is not often reported in children. The etiology is unknown, and symptoms resolve over time with supportive care. Usually only one site of swelling and tenderness is noted. Because of the rarity of this diagnosis in children, other causes of anterior chest pain and swelling, such as tumor, soft tissue infection, or osteomyelitis, must be excluded.

Pulmonary Causes

Pulmonary causes of chest pain include pneumonia[54] and reactive airways disease. Patients with pneumonia usually are febrile and tachypneic, and they may have pleural effusion, pneumothorax, or pneumomediastinum. Signs and symptoms of pulmonary disease include decreased breath sounds, dullness to percussion, rales, rhonchi, wheezes, and, rarely, chest wall crepitus.

Pulmonary embolus is rare but should be suspected in patients with any predisposing factor: central venous catheter, methicillin-resistant *S. aureus* infection, obesity, surgery, trauma, cancer, pregnancy, use of oral contraceptives, or inherited hypercoagulable state.[55,56] History of previous venous thrombosis also is a risk factor. Symptoms of pulmonary embolus include sudden onset of dyspnea, pleuritic chest pain, cough, and hemoptysis. Findings on physical examination include tachypnea and tachycardia, rales, and an audible S_4 with a loud S_2 heart sound. Chest radiographic findings are nonspecific. A number of tests have been used to diagnose pulmonary embolus, including serum D-dimer levels, ventilation-perfusion scanning, pulmonary angiography, helical CT, and magnetic resonance angiography.

Cardiac Causes

Pericarditis with pericardial effusion caused by bacterial, viral, fungal, or inflammatory disease is often associated with chest pain.

Pain can be located over the precordium or referred to the neck, shoulder, or left arm. Pain often is relieved when the patient bends forward. Physical examination may reveal distant heart sounds and a pericardial friction rub. Pulsus paradoxus is seen with cardiac tamponade. Echocardiogram is used to assess pericardial disease.

Myocardial infarction is rare in childhood.[57] Myocardial ischemia may occur as a result of anatomic or acquired heart lesions or arrhythmias. Anatomic lesions are often associated with a heart murmur. Myocardial ischemia can be seen with acquired heart disease caused by ARF, endocarditis, or viral myocarditis, trauma, or cocaine abuse. Children with Kawasaki disease and coronary artery aneurysms are at risk for coronary artery thrombosis with subsequent myocardial infarction. Presenting symptoms may include shock, vomiting, irritability, dyspnea, or abdominal pain. Older children are more likely to complain specifically of squeezing chest pain that may or may not radiate and shortness of breath. Diagnosis is made by electrocardiogram changes that include ventricular arrhythmias, ST-segment changes, and wide Q waves. Elevation of cardiac enzymes is noted in most cases, but is not as reliable an indicator of myocardial ischemia in children as in adults.

Other Causes

Gastrointestinal causes of chest pain include gastrointestinal reflux, presence of an esophageal foreign body, and caustic ulceration from oral medications (especially tetracyclines and nonsteroidal anti-inflammatory drugs) taken without sufficient fluid or just before lying down.

Marfan disease is an inherited disorder of connective tissue. Associated clinical findings include a history of subluxation of the lens of the eye, increased height and arm span, narrow fingers and toes, hypermobility of the joints, anterior chest wall deformities, and scoliosis. The most common cardiovascular complication is progressive enlargement of the aortic root predisposing to aortic aneurysm, dissection, or rupture.[58] Symptoms of a dissecting aortic aneurysm include sudden onset of substernal chest pain that radiates to the back or shoulders. Findings on physical examination can include a soft murmur over the aorta, tachycardia, hypotension, and poor perfusion. Echocardiography establishes the presence of dilation of the aortic root and ascending aorta and aortic or mitral valve insufficiency. Spontaneous pneumothorax also can be a feature of Marfan disease and an additional cause of chest pain.

Infections of the Oral Cavity

Jana Shaw

Immediately following birth, the mouth has a substantial microflora living in symbiosis with a healthy host.[1,2] Molecular methods of 16S DNA amplification reveal a tremendously diverse bacterial environment, largely uncharacterized.[2]

Odontogenic Infections

Tooth Infections

In health, *Streptococcus*, *Peptostreptococcus*, and *Veillonella* spp. and diphtheroids account for more than 80% of the total recoverable flora of the oral cavity. Quantitative studies indicate that anaerobes outnumber facultative bacteria 8-fold. Facultative gram-negative bacilli are uncommon in the healthy child but may become prominent in seriously ill patients.[3] Certain sites tend to adhere certain bacteria. For example, *Streptococcus salivarius* and *Veillonella* spp. have a predilection for the tongue and buccal mucosa and predominate before eruption of teeth.[4] In contrast *Streptococcus sanguinis, Streptococcus mutans,* and *Actinomyces viscosus* preferentially colonize the tooth surface, whereas *Fusobacterium*, *Prevotella,* and *Porphyromonas* spp. and anaerobic spirochetes are concentrated in the gingival crevices.[4]

Dental Caries

In the United States, caries are the most common chronic disease of childhood and are 5 times more common than asthma.[5] Caries of primary teeth commonly are referred to as *caries of early childhood*.[6] Plaque-related bacteria colonize the tooth surface and produce a weak acid during their carbohydrate metabolism.[7] Acid production lowers local pH and results in demineralization of the tooth with efflux of calcium, phosphorus, and carbonate.[8] Tooth colonization with cariogenic bacteria is a key factor for development of caries. Bacterial 16S sequence analysis has shown association of *S. mutans, S. salivarius, S. sobrinus*, and *S. parasanguinis* with early stages of caries, and *Veilonella* spp. were predictive of future caries among children without history of caries.[9] Lactobacilli are strongly associated with more advanced stages of caries.[10] With progression of caries severity, there is loss of healthy microbial community diversity.[9] The major reservoir from which infants acquire cariogenic bacteria is their primary caregiver, usually the mother.[11] Caries can affect any part of the tooth. In children, coronal caries typically have been found in the pits and fissures of the occlusal surfaces of molars and premolars. Food retention occurs less frequently at interproximal sites and the gingival margins, except in infants who fall asleep with a bottle of milk or juice. In early childhood the disease develops over smooth surfaces. Treatment consists of restoration of the affected tooth augmented by preventive methods such as fluoride treatments, flossing, tooth brushing, meticulous removal of the biofilm, placement of sealants, and avoidance of sugary snacks and drinks.

Pericoronitis

Pericoronitis is an acute localized infection associated with operculum of the gum overlying partially erupted teeth or impacted wisdom teeth. The third molars (wisdom teeth) often are affected, especially when their eruption is hindered by lack of space. The tissue around the tooth becomes red, edematous, and tender to touch, but the underlying bone usually is not involved. The patient reports continuous pain that ranges from dull to throbbing to intense, often radiating to the mouth, ear, throat, or the floor of the mouth. Other symptoms can include swelling of the cheek, trismus, dysphagia, and foul breath smell. Systemic manifestations can include fever, chills, and submandibular, submental, or cervical lymphadenopathy. Treatment consists of gentle debridement, irrigation under the operculum, and a systemic antibiotic effective against mouth flora, along with incision and drainage if infection spreads into soft tissue.[12]

Pulpitis and Periapical Abscess

Pulpal infection most frequently results from caries. Demineralization and destruction of the enamel is followed by invasion of the pulp to produce localized or generalized *pulpitis*. In early stages of infection (*reversible* pulpitis), patients typically complain of tooth sensitivity to percussion and thermal changes, especially cold drinks. Pain stops abruptly when the stimulus is withdrawn. The ongoing inflammation and built up pressure lead to pulp necrosis described as *irreversible pulpitis*.[13] Complications of pulpitis include spread of infection to the adjacent periodontal ligaments and invasion of the alveolar bone condition called *periapical abscess*. Serious complications of periapical infections are rare.[5] However, in some cases infection spreads, causing abscesses in the submaxillary triangle or in the parapharyngeal or submasseteric space.[6] In the maxilla, periapical infection can manifest in the soft tissues of the face. Infection also can extend to the infratemporal space, including the sinuses, and from there to the central nervous system, causing subdural empyema, brain abscess, or meningitis.[14]

The most common organisms isolated from infected pulp include aerobic, facultative anaerobic organisms (i.e., *S. salivarius*, other α-hemolytic streptococci, nonhemolytic streptococci) and anaerobic streptococci, anaerobic gram-negative bacilli, *Actinomyces* spp., *Propionibacterium* spp., *Veillonella* spp., and others.[15] Treatment consists of elimination of infected pulp (root canal treatment) or extraction of the tooth. Cochrane literature review found no evidence to support antibiotic use for treatment of pulpitis alone. There was no difference in pain perception or analgesic use among 40 patients with irreversible pulpitis randomly assigned to penicillin or placebo arm.[13] Antibiotic therapy is indicated if drainage cannot be performed or the infection has spread to surrounding soft tissues. Penicillin usually is adequate; amoxicillin-clavulanate and clindamycin are effective against β-lactamase –producing anaerobic bacteria.

Periodontal Infections

Periodontitis is inflammation that extends deep into the tissues and causes loss of supporting connective tissue (periodontium) and alveolar bone. Severe periodontitis can result in loosening of teeth, impaired mastication, and even tooth loss. Bacterial species reproducibly associated with disease include *Porphyromonas gingivalis, Tannerella forsythia, Aggregatibacter* (formerly *Actinobacillus*) *actinomycetemcomitans*, and *Treponema denticola*.[16] Histologically, nonprogressive inflammatory foci tend to be composed predominantly of T lymphocytes and macrophages, suggesting that the cell-mediated response can control disease. Destructive lesions are dominated by B lymphocytes and plasma cells, suggesting that humoral immunity, although documented by elevated immunoglobulin G levels against anaerobic organisms, is not always effective.[2,17]

Early-Onset Periodontitis

Juvenile (aggressive) peridontitis is a particularly destructive form of peridontitis seen in adolescents. Its localized form is characterized by rapid bone loss affecting the first molar and incisor teeth. The generalized form is rapidly progressive, affecting other teeth. Plaque is minimal, and specific defects in neutrophil chemotaxis and phagocytosis were demonstrated among 75% of patients. DNA probes and primers have revealed anaerobic organisms such as *A. actinomycetemcomitans, P. gingivalis, Prevotella intermedia, T. denticola,* and *T. forsythia*.[18] Treatment consists of systemic antibiotics. Narrow-spectrum antibiotics such as penicillin, amoxicillin, cephalexin, and macrolides are not effective against increasing number of β-lactamase–producing anaerobes. Antibiotics that include a β-lactamase inhibitor (i.e., clavulanate sulbactam) or clindamycin offer excellent coverage against most aerobic and anaerobic oral pathogens. The decision whether to use a narrow- or broad-spectrum antibiotic should be individualized.

Mucosal Infections

Gingivitis

Gingivitis is the most common periodontal disease during childhood with peak incidence near adolescence.[19] Inflammation is initiated by local irritation and bacterial invasion.[20] Bleeding of the gums after eating or brushing and fetor oris can be early signs of gingivitis. There usually is no pain. Treatment consists of plaque removal and good oral hygiene.[12]

Other Oral Infections and Conditions

Differentiating features of oral infections and other conditions encountered frequently are shown in Tables 25.1 and 25.2.

TABLE 25.1

Viral Infections of the Oral Cavity in Immunocompetent Individuals[a]

Agent	Acquisition	Usual Intraoral Site	Oral Manifestations
HERPES SIMPLEX VIRUS (HSV) TYPES 1 AND 2			
Primary gingivostomatitis	Saliva; direct contact with active lesions (oral, perioral, genital)	Anterior gingiva and mucosa, hard palate, tongue, lips	Vesicles, ulcers covered with yellowish exudates; gingival edema or erythema
Herpes labialis	Saliva; direct contact with active lesions (oral, perioral, genital)	Lips	Vesicles, ulcers and crusting
Recurrent intraoral herpes	HSV reactivation	Gingiva, hard palate	Vesicles, ulcers
Erythema multiforme	HSV reactivation	Buccal and labial mucosa, tongue, lips	Erythematous macules, vesicles, ulcers
VARICELLA-ZOSTER VIRUS (VZV)			
Chickenpox	Saliva, direct contact with active lesions	Hard and soft palate, buccal mucosa, tongue, lips	Vesicles, ulcers
Zoster	VZV reactivation	Palate, lips, tongue, buccal mucosa, gingiva	Unilateral vesicles, ulcers, bone necrosis, tooth exfoliation; pain along trigeminal nerve
EPSTEIN-BARR VIRUS (EBV)			
Infectious mononucleosis	Saliva	Hard and soft palate, gingiva	Lymphadenopathy, palatal petechiae, gingival necrosis, ulcers, edema of uvula
Oral hairy leukoplakia	Established EBV	Lateral borders of	Vertical white,

	infection	the tongue	hyperkeratotic lesions
Burkitt lymphoma	Not known	Maxilla, molar-premolar area	Tumors; loosening and displacement of teeth
Nasopharyngeal carcinoma	Not known	Nasopharynx	Keratinizing squamous carcinoma; nonkeratinizing squamous carcinoma; undifferentiated carcinoma
CYTOMEGALOVIRUS	Congenital; breastfeeding; saliva	Teeth	Enamel hypoplasia, dental attrition, discoloration
HUMAN HERPESVIRUS 8	Possibly sexual transmission	Hard and soft palate	Kaposi sarcoma
COXSAKIEVIRUSES			
Hand-foot-and-mouth disease	Saliva	Buccal and labial mucosa, tongue	Vesicles, ulcers
Herpangina	Saliva	Soft palate	Vesicles, ulcers
HUMAN PAPILLOMAVIRUSES			
Condyloma acuminata	Direct contact with lesions	Tongue, gingiva, labial mucosa, palate	Soft, broad-based papules with a pebble-like surface
Focal epithelial hyperplasia (Heck disease)	Direct contact with lesions; self-inoculation	Alveolar mucosa, lips	Soft, flat, nonpedunculated papules, usually with a pebble-like surface
Squamous cell papilloma	Transformation chronic infection	Uvula, hard and soft palate, tongue, frenulum, lips, buccal mucosa, gingival	Soft, pedunculated, exophytic papules with cauliflower-like surface
Verruca vulgaris	Direct contact with lesions, self-inoculation	Lips, tongue, labial mucosa, gingiva	Firm, broad-based elevated papules with cauliflower-like surface
MOLLUSCUM CONTAGIOSUM	Direct contact with lesion	Lips	Waxy, dome-shaped papules
MEASLES	Saliva, respiratory droplets	Buccal and labial mucosa; teeth	Bluish-white macules surrounded by erythema (Koplik spots); pitted enamel
MUMPS	Saliva, respiratory droplets	Salivary glands	Swelling of salivary glands; erythema and edema of Wharton and Stensen duct openings; oral dryness
RUBELLA	Saliva, respiratory droplets	Hard and soft palate	Petechiae; small dark-red papules (Forchheimer sign)
HEPATITIS C VIRUS	Blood, sexual transmission	Buccal mucosa	Lichen planus

TABLE 25.2

Oral Mucosal Manifestations of Local and Systemic Infection and Other Conditions

Cause	Lesion	Site	Disease Course/Comment
BACTERIA			
Scarlet fever *(Streptococcus pyogenes)*	Strawberry tongue	Tongue	Reddened edematous papillae project through white coating; coating peels off to leave red glistening tongue with prominent papillae
	Punctiform and petechial lesions	Palate	Intraoral erythema; uvula and free margin of soft palate red and edematous; lips uninvolved
Toxic shock syndrome *(Staphylococcus aureus)*	Intraoral erythema, edema, and desquamation	Lips, all intraoral mucous membranes	Can progress to painful desquamation
Treponema pallidum	Painless ulcer with rolled edges	Anywhere on oral mucous membranes	Primary chancre heals over 5–10 days; followed by systemic manifestations if untreated
Gingivitis	Edema, thickening, erythema, and easy bleeding; usually painless	Gingiva and interdental papillae	Subgingival plaque always present; common in children, particularly during puberty
Acute necrotizing ulcerative gingivitis	Pseudomembranes (necrosis of papillae)	Gingiva	Necrosis of interdental papillae results in marginated, punched-out, eroded appearance; grey necrotic pseudomembranes; fusiform bacilli and spirochetes consistently found
Cystic gingival lesions	Red, cystic lesion, 4–10 mm	Gingival ridge	Infants <10 mo with pneumococcal bacteremia
Glossitis	Swollen, red, painful	Tongue	*Streptococcus pyogenes, Staphylococcus aureus, Haemophilus influenzae* b
Uvulitis	Red, edematous	Uvula	*Streptococcus pyogenes, Haemophilus influenzae* b; can cause respiratory compromise
FUNGUS			
***Candida* spp.**	Pseudomembranes of creamy white plaques on erythematous mucosa	Tongue, gingiva, buccal mucosa; rarely, pharynx, larynx, esophagus; cheilitis	Lesions can be painless, can burn, or can feel sore or dry
Histoplasma capsulatum	Ulcers	Oropharynx	Occurs with subacute or chronic disseminated disease
UNKNOWN			
Kawasaki disease	Strawberry tongue; mucosal erythema; erythema, cracking peeling, bleeding lips	Tongue, oropharynx, lips	Mucosal erythema present in all but atypical forms
Recurrent oral ulcerations (aphthous stomatitis)	Shallow, circular painful ulcer <5 mm on erythematous base with pseudomembrane	Nonkeratinized movable labial and buccal mucosa; tongue and floor of mouth	Healing occurs after 4 days; common (incidence 20%); recurrences 12 times/yr; etiology unknown; symptomatic therapy

	Deep ulcers of >5 mm diameter; painful	All areas of oral cavity	Lasts 6 wk–3 mo; heals with scarring (Sutton scarring aphthae)
	Small cluster of vesicles; extremely painful; no erythematous border	Tip and lateral margins of tongue	Herpetiform ulcers with no relationship to HSV
PFAPA syndrome	Small ulcers	Oral mucosa	Syndrome of recurrent fever, aphthous stomatitis, pharyngitis, and cervical adenitis; affects children <5 yr; recurrence every 2–9 wk
Gangrenous stomatitis (noma)	Focal, destructive lesions	Gingiva and deeper structures	Rare, acute, fulminating in severely debilitated and malnourished children; spirochetes and other anaerobic bacteria may be involved
Cyclic neutropenia and agranulocytosis	Small ulcers	Oral mucosa	
Drug- or radiation-induced stomatitis	Ulcers and pseudomembrane formation; painful	Nonkeratinized labial and buccal mucosae; soft palate; floor of mouth; ventral and lateral tongue surfaces	Microbiologic diagnosis important to rule out viral reactivation or bacterial superinfection
Behçet syndrome	Ulcers	Oral mucosa	Multisystem disease that can involve many mucous membranes
Stevens-Johnson syndrome	Macules, papules, vesicles, bullae	Buccal mucosa and vermilion border of the lips; relative sparing of gingivae	Erythema multiforme exudativum; 25% of cases confined to oral mucosa; lesions appear in crops; complete healing 4–6 wk; can cause recurrent stomatitis and labiitis
Inflammatory bowel disease	Ulcers (aphthous-like)	Oral mucosa	Manifestation of multisystem disease

PFAPA, periodic fever with aphthous stomatitis, pharyngitis, and adenitis.

Herpes Simplex Virus Gingivostomatitis

Herpes simplex virus (HSV) gingivostomatitis is the most recognized viral infection of the oral cavity. Primary infection with HSV-1 occurs throughout childhood, most commonly between the ages of 6 months and 5 years, and during adolescence and results in seropositivity in up to 90% of adults.[21,22] Up to 90% of children with primary HSV infections are symptom free.[23] After primary infection, the virus remains dormant in trigeminal ganglion and reactivates after stressful stimuli (i.e., cold, trauma, sunlight, intercurrent illness). Recrudescent disease has been estimated to occur in up to 40% of seropositive individuals.[24] HSV infection is ubiquitous and transmitted from symptomatic and asymptomatic people with primary or recurrent infection. Infections with HSV-1 usually result from direct contact with infected oral secretions. The incubation period for HSV infection beyond the neonatal period is usually 2 days to 2 weeks.[25] In primary infection, vesicles appear on the first day of illness in 85% of affected children and can persist for 7 to 18 days.[26] Primary symptomatic infections are accompanied by fever, lymphadenopathy, malaise, pharyngitis, and anorexia. Gingiva are red, swollen, and bleeding. Small vesicles surrounded by a red halo on the gingiva and anterior lingual and buccal mucosa rapidly rupture and coalesce, giving rise to ulcerations. HSV gingivostomatitis is painful, and children commonly refuse to swallow, resulting in drooling. Differential diagnosis includes coxsackievirus infection (herpangina), erythema multiforme, pemphigus vulgaris, acute necrotizing ulcerative gingivitis, and most commonly aphthous stomatitis.

Complications of HSV gingivostomatitis include dehydration, herpetic whitlow or herpetic keratitis from autoinoculation, and secondary bacteremia with oral flora.[27,28] Recurrent HSV orolabial lesions occur in one third of individuals with prior HSV infection. Reactivation lesions typically are found around the gingiva, hard palate, and vermilion border of the lip ("cold sore"). A prodrome of tingling, burning, and itching occurs 12 to 36 hours before the eruption of the vesicles. Viral shedding persisted for a mean of 7 days (range, 2–12 days) among 36 untreated immunocompetent children in one study.[29]

Treatment of HSV gingivostomatitis usually is palliative, with hydration and pain control. Topical application of diphenhydramine, simethicone (Maalox), bismuth subsalicylate (Kaopectate), or viscous lidocaine is frequently prescribed; however, their usefulness and benefit have been questioned.[29] A randomized, double-blind treatment trial in children using oral acyclovir during early stages reduced the duration of symptoms, improved healing, and reduced infectivity[30] (see Chapter 204). A systematic review showed weak evidence that oral acyclovir offered treatment benefit.[31] In general, most experts would treat patients who come to attention early, within 72 to 96 hours of the onset of symptoms, or who have severe disease. Chronic suppressive therapy can be used to reduce recurrences, such as in patients with facial, periorbital, or ocular lesions or very frequent episodes.[25] Among healthy subjects, combination of early topical acyclovir 5% and hydrocortisone 1% cream (ME-609) was more effective in reducing progression to ulcerative HSV lip lesions and reduced the size of the lesions compare with topical acyclovir or placebo.[32]

Oral Candidiasis

Oral candidiasis usually is caused by *Candida albicans* and has several manifestations such as pseudomembranous candidiasis, angular cheilitis (perlèche) and erythematous atrophic candidiasis (glossitis).

Pseudomembranous Oral Candidiasis (Thrush).

Neonates typically are colonized by *Candida* spp. during passage through the birth canal. Other sources of transmission to neonates include colonized skin of breasts (for breastfed infants) or hands and improperly cleaned bottle nipples. *Candida* spp. are asymptomatically carried in the gastrointestinal tract of many healthy children and premature infants as well as in patients treated with antibiotics and in those who are receiving chemotherapy, radiation therapy, or inhaled glucocorticoids. Thrush that is more than mild, which occurs beyond 6 months of age in the absence of risk factors, should prompt evaluation for human immunodeficiency virus (HIV) infection, cell-mediated immunodeficiency, neutropenia, or other phagocytic defect.[33] The pseudomembranous form of candidiasis is most common and is characterized by white plaques on the buccal mucosa, palate, tongue, or oropharynx. The plaques can be wiped off to reveal a red, raw, painful surface. Many patients with oral candidiasis are asymptomatic. Symptomatic patients can complain of feeling of “cotton” in the mouth, loss of taste, and sometimes pain during eating and swallowing. The diagnosis of pseudomembranous candidiasis usually is suspected clinically and is readily confirmed by scraping the lesions with a tongue depressor and preparing a slide for Gram stain or KOH preparation. Thrush is the most common oral manifestation of HIV, with reported prevalence ranging between 20% and 72%.[34–36] Thrush (which usually is extensive) can be the initial indication of HIV infection in a patient who appears otherwise healthy.[37] Topical agents (nystatin oral suspension or clotrimazole troches or pastilles) are recommended for initial therapy of mild oral candidiasis, including in immunocompromised children. Systemic therapy with fluconazole should be considered for patients with severe disease, immunocompromised patients (including those with HIV), and patients who fail to improve with topical treatment.[38,39] Patients not responding to treatment with oral or intravenous (IV) fluconazole should be treated with voriconazole, posaconazole, itraconazole, or amphotericin.

Patients with candidial angular cheilitis present with painful fissuring of the corner of their mouth. Risk factors for cheilitis include habitual licking of the corners of the mouth or immunosuppression. Other causes of cheilitis include bacterial and viral infections (i.e., *S. aureus*, HSV), nutritional deficiencies, anemia, allergy, and bruxism. Treatment is similar to that for thrush along with behavioral modification to minimize licking.

Erythematous atrophic candidiasis is characterized by red painful flattened tongue papillae in the dorsum of the tongue or erythema of soft and hard palate. This condition most commonly occurs after disruption of the oral mouth microbiota (i.e., after antibiotic use). Treatment is similar to that for other forms of oral candidiasis.

Acute Necrotizing Ulcerative Gingivitis

ANUG, also known as *Vincent disease* or *trench mouth*, has a sudden onset with gingiva showing punched-out crater-like ulcerations, covered with a whitish pseudomembrane, surrounded by a demarcated zone of erythema. Any area of the mouth can be affected. There is spontaneous bleeding, and breath has fetid odor. The patient's chief complaint is pain. Bacterial overgrowth of oral *Treponema* and *Selenomonas* spp., *P. intermidia,* and *Fusobacterium* spp. contribute to the infection.[40] However, other factors are believed to contribute to the disease.[41] Systemic penicillin and metronidazole are commonly used in addition to an oral antiseptic rinse such as chlorhexidine and good mouth care.[42]

Periodontitis, Gingivitis, and Mucositis in Immunocompromised Hosts

HSV infection in immunocompromised hosts has a higher risk for dissemination and a longer duration of outbreaks and is less responsive to therapy.[43] Complications include esophagitis, tracheobronchitis, pneumonitis, bacteremia, hepatitis, and pancreatitis.[26,27,44–46] Among HIV-infected children with orolabial HSV infection, initial therapy with oral acyclovir is recommended. Children with severe HSV disease or immunosuppression (other than HIV) should be treated with IV acyclovir. Children with recurrent HSV orolabial lesions should be treated with short courses of oral acyclovir, valciclovir, or famciclovir. Alternatively, children with severe and frequent HSV orolabial exacerbations may benefit from daily chronic suppressive therapy.[47] Neonatal HSV skin-eye-and-mouth disease is discussed elsewhere.

Chemotherapy- and radiotherapy-induced mucositis is the result of a breakdown of the mucosal epithelium, ulceration, and bacterial overgrowth in the presence of granulocytopenia. Gram-negative bacteria and α-hemolytic streptococci are important causes of complicating septicemia in patients with mucositis.[48] A Cochrane database systematic review and meta-analysis of randomized trials of 9 interventions (allopurinol, aloe vera, amifostine, cryotherapy, IV glutamine, honey, keratinocyte growth factor, laser, and polymixin-tobramycin-amphotericin antibiotic pastille or paste) showed some statistically significant evidence of benefit (albeit weak) for preventing and reducing severity of mucositis in cancer patients.[49] Trial of a novel drug, palifermin, and a randomized control trial of visible-light therapy in hematopoietic stem cell transplant recipients also showed benefit.[50,51] Palifermin is now recommended for prevention and treatment of mucositis for patients undergoing high-dose chemotherapy with or without radiation therapy followed by bone marrow transplantation for hematologic cancers.[52]

Human Immunodeficiency Virus–Associated Oral Lesions

The pathogenesis of oral lesions in children with HIV is not well characterized. The combination of lymphopenia, low $CD4^+$ lymphocyte counts, humoral dysregulation, and phagocytic defect most likely contributes to the array of infectious complications. In 1992 a European and US expert panel developed a classification system and diagnostic criteria for HIV-associated lesions.[53] A simplified summary is provided in Box 25.1.

Box 25.1

Classification of Human Immunodeficiency Virus–Associated Oral Lesions

Lesions Strongly Associated With HIV Infection

- Candidiasis
  - Erythematous
  - Pseudomembranous
- Hairy leukoplakia
- Kaposi sarcoma
- Non-Hodgkin lymphoma
- Periodontal disease
  - Linear gingival erythema
  - Necrotizing ulcerative gingivitis
  - Necrotizing ulcerative periodontitis

Lesions Less Commonly Associated With HIV Infection

- Bacterial infections (*Mycobacterium avium* complex)
- *Mycobacterium tuberculosis*
- Melanotic hyperpigmentation
- Necrotizing (ulcerative) stomatitis
- Salivary gland disease (xerostomia, swelling of major salivary

glands)

Thrombocytopenic purpura

Ulceration (not otherwise specified)

Viral infections (herpes simplex virus, human papillomavirus, varicella-zoster virus)

Modified from Kline WM. Oral manifestations of pediatrics human immunodeficiency virus infection: a review of literature. Pediatrics 1996;97:380–388.

Besides oral candidiasis, parotid enlargement occurs commonly in HIV infection, with prevalence of 47% reported from a large study of HIV-infected children from the US.[54] Periodontal disease, hairy leukoplakia, and aphthous ulcers have been reported rarely.[55] Several forms of periodontal disease, such as linear gingival erythema and necrotizing ulcerative gingivitis, are strongly associated with HIV infection.[38] Treatment of HIV-associated HSV and *Candida* infections was described earlier.

Complications of Odontogenic and Mucosal Infections

Ludwig Angina

The classic description of Ludwig angina includes rapidly spreading indurated cellulitis of the submandibular and sublingual spaces bilaterally without abscess formation. Infection starts in the floor of the mouth. Dental infection is found in 50% to 90% of reported cases.[12,56] Trauma to the oral cavity, piercing, or laceration preceded infection among a number of reported cases. Clinically, patients demonstrate brawny, board-like swelling in the submandibular spaces that does not pit on pressure. The mouth is held open, and the floor is elevated, pushing the tongue to the roof of the mouth. Eating and swallowing are difficult, and respiration can be impaired by obstruction of the tongue. Rapid progression can result in edema of the neck and glottis and can precipitate asphyxiation. Fever and toxicity usually are present. Treatment requires high doses of antibiotics active against oral flora, airway monitoring, early intubation or tracheostomy when required, dental care, soft tissue decompression, and surgical drainage. Systemic penicillin, ampicillin, and amoxicillin are appropriate choices for less severe infection or when susceptibility of the organism is known. However, their utility is limited owing to the production of β-lactamase by many oral anaerobes.[57] Antimicrobial resistance among anaerobes has been steadily increasing, and consequently susceptibility cannot be predicted for some highly virulent isolates (i.e., *Bacteroides, Prevotella, Fusobacterium,* and *Clostridium* spp.). Hence antibiotics containing clavulanate, sulbactam, or tazobactam component or carbapenems are recommended for severe oral infections.

Suppurative Jugular Thrombophlebitis (Lemierre Syndrome)

The incidence of Lemierre syndrome decreased dramatically after its original description by Andre Lemierre in 1936 but has had apparent resurgence.[58] The syndrome includes septic thrombophlebitis of the internal jugular vein, usually secondary to an acute oropharyngeal infection, and frequently is complicated by bloodstream and metastatic infection. The usual agent is *Fusobacterium necrophorum*, but *S. aureus* and *Streptococcus pyogenes* are occasional causes[59] (see Chapter 28). Most cases occur in adolescents and young adults with tonsillopharyngitis as the primary infection. Odontogenic infections, sinusitis, and otitis externa have been reported as primary infections in a few patients with Lemierre syndrome.

Infections of the Salivary Gland

Bilateral asymptomatic enlargement of the parotid gland usually is due to a noninfectious cause. The differential diagnosis includes metabolic and endocrine disorders such as malnutrition (vitamins B_6 and C deficiencies), chronic pancreatitis, obesity, cystic fibrosis, thyroid disease, and diabetes mellitus. Infections of the salivary glands (including the parotid) are discussed later.

Acute Suppurative Sialadenitis

In contrast to adults, children commonly incur repeated episodes of acute sialadenitis.[60] The parotid gland is affected more commonly than the submandibular gland, and more than one gland can be affected during a single episode.[61] Primary etiology appears to be salivary stasis. Predisposing factors may include calculi, duct stricture, dehydration, infancy, autoimmune disease, and congenital sialectasia. Clinical manifestations include local pain, tenderness, and edema of the soft tissue overlying the affected gland. A purulent discharge can be seen draining from the duct of the involved gland. Most children remain nontoxic during acute episodes.[60] Residual induration and enlargement of the gland can persist for months after the initial infection. Treatment consists of systemic antibiotics, local heat and massage, fluids, and sialagogues. *S. aureus* is the most common infectious cause. In addition, direct needle aspiration has confirmed α-hemolytic streptococci, *H. influenzae*, *S. pyogenes*, *Streptococcus pneumoniae*, *Moraxella catarrhalis*, *Escherichia coli*, and anaerobic bacteria as causative.[61,62] Mycobacterial and fungal parotitis cases also have been described rarely. Acute sialadenitis infrequently progresses to abscess formation. The patient should be monitored closely for spread of infection into contiguous fascial spaces of the neck.[63] Recurrent parotitis is associated with poor oral hygiene and underlying disease such as abnormal ductal architecture, allergies, immunoglobulin A deficiency, and HIV.[64–66] *S. pneumoniae* was isolated from parotid gland pus in a patient with HIV infection.[64] Empiric therapy should include a penicillinase-resistant antistaphylococcal antibiotic, as well as consideration of local prevalence of methicillin-resistant *S. aureus*. Purulent discharge from the gland's duct on the buccal mucosa should be cultured to guide antimicrobial therapy.

Neonatal Sialadenitis

Neonatal suppurative sialadenitis is an uncommon but recognizable disease with a prevalence of 3.8 per 10,000 hospital admissions in one report.[67] Neonatal sialadenitis much more commonly affects the parotid gland than the submandibular gland. Presence of calculi or anatomic deformities of the oral cavity, dehydration, and prematurity are established risk factors in sialadenitis in this age group. Ismail and colleagues[68] reviewed case reports since 1970, which included 44 cases of neonatal parotitis. Approximately 32% of neonates with parotitis were born prematurely. The most common causative organism was *S. aureus*. Other organisms identified included viridans streptococci, *E. coli, Pseudomonas aeruginosa*, *M. catarrhalis*, peptostreptococci, *Bacteroides* spp., *Prevotella* spp., and coagulase-negative staphylococci.[68] Salivary secretions should be cultured and Gram stain obtained. Disease usually is limited to one gland, and signs and symptoms of systemic disease may not be present. Physical examination reveals a warm, tender, erythematous mass; pus can be expressed from the parotid or salivary duct. Laboratory test abnormalities are nonspecific. Leukocytosis with neutrophil predominance was found in 69% of the 44 cases. Serum amylase was measured in 16 of 44 cases and was elevated in only 4 (25%) of cases.[68] Adequate hydration and antibiotic therapy was successful in most cases. If prompt clinical improvement does not occur, ultrasonography may reveal the presence of an intraparotid abscess.

Viral Parotitis

The most common cause of viral parotitis is mumps virus. The disease is seen most frequently during spring and winter months. The incubation period is 16 to 18 days, and the contagious period includes 1 to 2 days before until 5 days after the onset of parotid swelling.[69] The prodrome includes malaise, fever, and sore throat with chills. The major salivary glands become tender. The patient may have trismus and difficulty chewing. The duct orifice may be swollen; saliva is clear. The white blood cell count is normal or slightly elevated with lymphocytosis. The diagnosis is based on clinical manifestations, but culture and serologic tests can be used for the diagnosis. Differential diagnosis includes other viral infections such as influenza, parainfluenza virus types 1 and 3, coxsackievirus types A and B, echoviruses, Epstein-Barr virus, cytomegalovirus, lymphocytic choriomeningitis virus, HSV-1, HIV, human herpesvirus 6, and bacterial causes (see earlier). Noninfectious causes of parotitis include Sjögren syndrome and metabolic, endocrine, and neoplastic disorders. People with parotitis without apparent cause should undergo diagnostic testing to confirm mumps infection[69] (see Chapter 224). Early recognition of the disease and outbreaks is important; reverse transcriptase polymerase chain reaction testing for mumps virus is available through many state laboratories.[70,71]

Juvenile Recurrent Parotitis

Juvenile recurrent parotitis (JRP) is the second most common salivary gland disease in children. A variety of causative factors have been proposed, including congenital ductal malformations, hereditary-genetic factors, viral or bacterial infection, allergy, and local manifestation of an autoimmune disease. A review of published literature shows all cases before puberty.[72,73] Clinical symptoms of JRP include recurrent, nonobstructive, nonsuppurative parotid inflammation. JRP usually is unilateral, but bilateral exacerbations can occur. Patients with HIV infection can manifest recurrent or chronic sialadenitis; cytomegalovirus and *S. pneumoniae* have been associated. Treatment of an acute episode generally includes early antibiotic therapy to prevent further parenchymal damage, adequate fluid intake, massage and warm compresses, and use of gum and other sialagogues. Salivary endoscopy affords opportunity for diagnosis and treatment and proved effective among 70 children with JRP with only 5 patients experiencing recurrence.[74] Performing sialography with dilation and hydrocortisone lavage along with parenteral amoxicillin-clavulanate therapy was reported to be useful in relieving symptoms in 26 children with JRP.[73]

Granulomatous Parotitis

Granulomatous diseases can be associated with chronic inflammatory parotitis. Children are affected infrequently.[63] Patients usually have localized nodules, which should be distinguished from malignancy. The mass usually is painless and slowly progressive, and often has no surrounding erythema. Saliva is normal in color. Sialography demonstrates extrinsic pressure on the ductal system without intrinsic abnormalities. Possible causes include sarcoidosis, cat-scratch disease, actinomycosis, tuberculosis, and nontuberculous mycobacterial infection. Excision of the gland is diagnostic and therapeutic. *Mycobacterium tuberculosis* infection of the gland is part of a systemic disease and requires systemic therapy.

Osteomyelitis

Mandibular Osteomyelitis

Osteomyelitis of the mandible is rare. Clinical manifestations include fever, facial swelling, and jaw pain, usually accompanied by the finding of a carious tooth. Surgical drainage of dental abscess, along with antibiotic therapy, usually results in a clinical cure. Treatment is given for a minimum of 4 weeks.[12]

Actinomycosis is an infrequent cause of mandibular osteomyelitis. Compilation of 19 pediatric cases over three decades showed a median age of 7 years, and 58% were females. Nearly 50% of patients had a history of recent tooth extraction, loss of a tooth with periodontitis, tooth abscess, or trauma with a pencil.[75] All cases presented with firm painful mass over the mandible. All cases required at least 1 surgical debridement in addition to prolonged antibiotic courses (several months).[75] Unfortunately, relapses are common. In such instances, additional debridement and cultures should be performed to direct antibiotic therapy. Actinomycosis may resemble a malignant process. Biopsy with anaerobic culture of the properly collected specimen to avoid contamination with commensal oral flora establishes the diagnosis. Microbiology laboratory personnel should be notified when actinomycosis is suspected in order to hold culture specimens under anaerobic conditions for 14 days. High-dose penicillin is the drug of choice; alternatives include clindamycin, erythromycin, and tetracyclines. The duration of antibiotic therapy depends on the extent and severity of infection, with minimum of 6 months.

Infantile Maxillary Osteomyelitis

Infantile maxillary osteomyelitis is rare, usually occurring in infants younger than 12 weeks.[66] It is an acute bacterial infection of the maxilla with necrosis and sequestration of the surrounding structures. Clinical findings can simulate orbital cellulitis, including chemosis, fever, proptosis, and purulence at the inner or outer canthus. The palate on the affected side is swollen, and the alveolar dental ridge is markedly thickened.[76,77] *S. aureus* is the usual pathogen. The condition can be mistaken for orbital cellulitis. Correct diagnosis is imperative for proper management and the prevention of complications, such as extension intracranially, optic nerve damage, disfiguring scarring of the face, and damage to the developing teeth. Surgical drainage and antibiotic therapy are mainstays of management.

Garré Osteomyelitis

Garré osteomyelitis, also known as *nonsuppurative ossifying periostitis* and *periostitis ossificans*, is a chronic nonsuppurative, sclerosing osteomyelitis. This condition usually is associated with a carious tooth, periodontal defect, or other type of low-grade inflammatory process (erupting molars).[78] The disease usually appears as an asymptomatic, unilateral swelling of the mandible in children and young adults. Clinical and radiographic findings, frequently showing laminated or onion skin appearance, are suggestive but not pathognomic. Differential diagnosis includes cortical hyperostosis (Caffey disease), osteosarcoma, and Ewing sarcoma. Histologic examination is necessary to establish a definite diagnosis. In general, the clinical course usually has sudden onset, with progression, spontaneous regression, and remodeling. Resolution is enhanced by the dental extraction and removal of the inflamed tissue.

The Common Cold

Diane E. Pappas

The common cold, also known as upper respiratory tract infection (URI), is an acute, self-limited viral infection of the upper airway that also may involve the lower respiratory tract. The characteristic symptom complex consisting of rhinorrhea, nasal congestion, and sore or scratchy throat is familiar to all adults.

Colds are the most common cause of human illness and are responsible for significant absenteeism from school and work. Children are especially susceptible because they have not yet acquired immunity to many of the viruses, they have poor personal hygiene practices, and they have frequent close contact with other children who are excreting virus.

Etiology

Colds are common because some of the causative viruses do not produce lasting immunity after infection and some viruses have numerous serotypes (Table 26.1). Cold viruses that do not produce lasting immunity include respiratory syncytial virus (RSV), parainfluenza viruses (PIVs), and human coronaviruses (HCoVs). Cold viruses that have numerous serotypes but produce lasting serotype-specific immunity after infection include rhinoviruses, adenoviruses, influenza viruses, and enteroviruses.[1]

TABLE 26.1

Immunity to Common Cold Viruses

Virus	No. of Serotypes
LONG-LASTING IMMUNITY NOT PRODUCED BY INFECTION[a]	
Respiratory syncytial virus (RSV)	1
Parainfluenza virus	4
Human coronavirus	2
IMMUNITY PRODUCED BY INFECTION[b]	
Rhinovirus	>100
Adenovirus	≥33
Influenza	3[c]
Echovirus	31
Coxsackievirus group A	3
Coxsackievirus group B	6

[a] Repeated infection with the same serotype is usual.

[b] Reinfection with the same serotype is uncommon.

[c] Type A subtypes change.

Modified from Hendley JO. Immunology of viral colds. In: Veldman JE, McCabe BF, Huizing EH, et al (eds). Immunobiology, Autoimmunity, Transplantation in Otorhinolaryngology. Amsterdam: Kugler Publications; 1985, pp. 257–260.

With at least 100 serotypes, rhinoviruses are the most common cause of URIs in children and adults. At least 50% of colds in adults are caused by rhinoviruses. Other viruses that cause URIs are HCoVs, RSV, human metapneumovirus, influenza virus, parainfluenza viruses, adenoviruses, echoviruses, and coxsackieviruses A and B. Human bocavirus (HBoV), discovered in 2005, has been reported in children with symptomatic URIs (>10%) but may also occur in asymptomatic children, making its role in causing illness unclear.[2–4]

Some viruses cause characteristic syndromes. For example, RSV causes bronchiolitis in children 2 years or younger, influenza viruses cause febrile respiratory illness with severe lower respiratory tract involvement, adenoviruses cause pharyngoconjunctival fever, parainfluenza viruses cause croup in young children, HBoV is associated with wheezing, and enteroviruses cause a variety of illnesses, including aseptic meningitis and herpangina.

Epidemiology

In temperate climates in the northern hemisphere, the predictable yearly epidemic of colds begins in September and continues unabated until spring. This sustained epidemic curve is a result of successive waves of different respiratory viruses moving through the community (Fig. 26.1). The epidemic begins with a sharp rise in the frequency of rhinovirus infections in September (after children return to school), which is followed by PIVs in October and November. RSV and HCoVs circulate during the winter months, and infection due to influenza virus peaks in the late winter. The epidemic ends with a small resurgence of rhinovirus infections in the spring. Adenovirus infection occurs at a constant rate throughout the cold season.

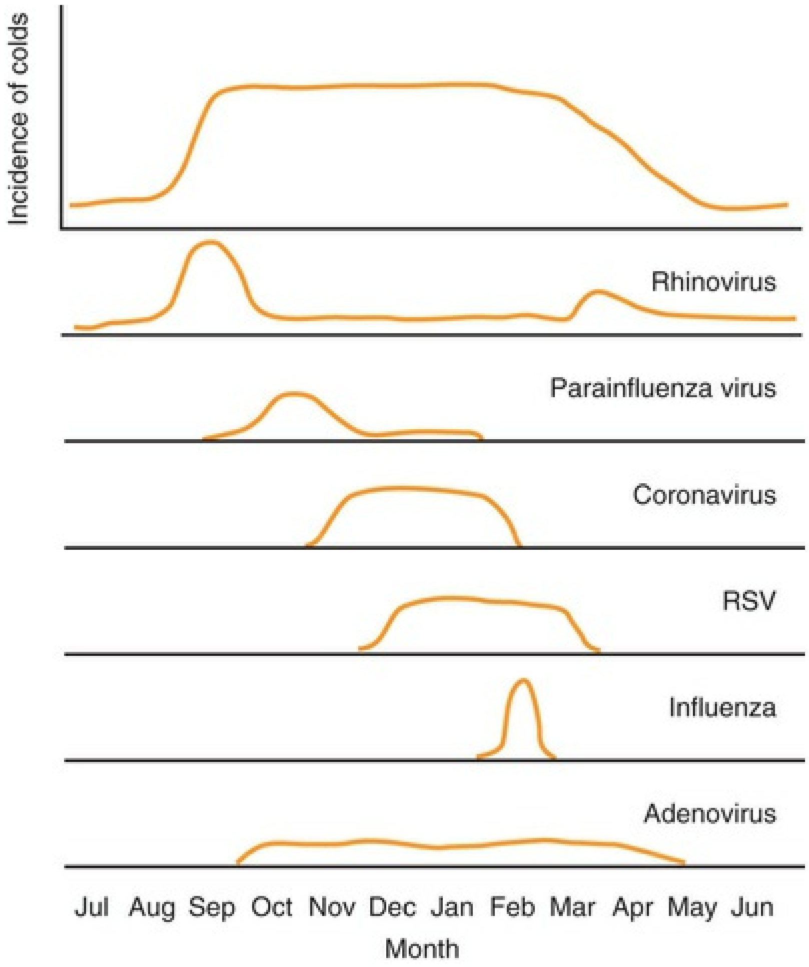

FIGURE 26.1 Schematic diagram of the incidence of colds and frequency of causative viruses. RSV, respiratory syncytial virus. (Modified from Hendley JO. The common cold. In: Goldman L, Bennett JC (eds). Cecil Textbook of Medicine, 21st ed. Philadelphia: WB Saunders; 2000, pp. 1790–1793.)

The frequency of colds varies with age. A 10-year study in the 1970s of families with children who did not attend a childcare facility showed that the peak incidence of colds occurs in preschool children 1 to 5 years old, with a frequency of 7.4 to 8.3 colds per year.[5] In a 52-week longitudinal study of 108 individuals in 26 households in Utah, which included diaries of illness and testing of weekly self-collected or family-collected anterior nares specimens by FilmArray, an automated polymerase chain reaction (PCR) system for virus detection, respiratory symptoms were identified for 38% of person-weeks for children younger than 5 years and 20% for older children and adults. Sixty percent of respiratory illnesses were associated with virus detection, but only approximately 50% of virus detections were associated with symptoms (especially rhinovirus and bocavirus).[6]

Viral transmission occurs primarily in the home setting, although the exact mechanism of spread has not been established. Colds can be spread by a small-particle (<5 μm in diameter) aerosol, which infects when inhaled; by large-particle (>10 μm in diameter) droplets, which infect by landing on nasal or conjunctival mucosa; or by direct transfer through hand-to-hand contact.[7] A small-particle aerosol is an effective method of transfer for influenza virus[8] and coronavirus[9] but not for RSV.[10] Rhinoviruses are most likely spread by large-particle droplets or direct transfer.

Rhinoviruses can survive as long as 2 hours on human hands and up to several days on other surfaces. Studies have shown that infected young adults commonly have rhinovirus on their hands, which can be efficiently transferred to the hands of uninfected individuals during brief contact. Infection results when the uninfected person transfers the virus from the hands on to his or her nasal or conjunctival mucosa. Sneezing and coughing are ineffective modes of rhinovirus transmission,[11] although there is some evidence that the virus also can be transmitted by aerosols generated by coughing, talking, and breathing.[12] Inoculation of the oral mucosa with rhinovirus[13] or RSV[14] does not result in infection.

Pathogenesis

Symptoms of the common cold do not appear to result from destruction of nasal mucosa because nasal biopsy specimens from young adults with natural and experimentally induced colds show intact nasal epithelium during symptomatic illness.[15,16] Study by in situ hybridization of nasal biopsy specimens obtained during rhinovirus infection indicates that replication occurs in only a small number of epithelial cells.[17,18] In vitro studies have shown that rhinovirus and coronavirus produce no detectable cytopathic effect when replicating in a cultured monolayer of nasal epithelial cells, whereas influenza virus A and adenovirus produce obvious damage.[19]

The symptoms of the common cold appear to result from release of cytokines and other mediators from infected nasal epithelial cells and from an influx of polymorphonuclear cells (PMNs). Nasal washings of volunteers experimentally infected with rhinovirus showed a 100-fold increase in PMN concentration 1 to 2 days after inoculation.[20] The influx of PMNs coincides with the onset of symptoms and correlates with a colored nasal discharge.[21] A yellow or white nasal discharge may result from the higher number of PMNs, whereas the enzymatic activity of PMNs (due to myeloperoxidase and other enzymes) may cause a green nasal discharge.

A potent chemoattractant for PMNs is produced by cells in culture infected with rhinovirus.[22] The chemoattractant has been identified as interleukin-8 (IL-8).[23] Elevated levels of IL-8 and other cytokines (e.g., IL-1β, IL-6) also have been demonstrated in the nasal secretions of infected individuals.[24,25] Elevated levels of albumin and kinins (predominantly bradykinin) in nasal secretions coincide with the onset of symptoms in experimental rhinovirus infection.[20] The elevated concentration of albumin and kinins likely results from exudation of plasma proteins due to greater vascular permeability in the nasal submucosa. The method by which viral infection initiates this vascular leak has not been determined. The release of kinins resulting from plasma exudation may augment the symptoms of the cold. Bradykinin alone can cause rhinitis and sore throat when sprayed into the noses of uninfected individuals.[26]

The paranasal sinuses usually are involved during an uncomplicated cold. In one study, CT scans obtained during the acute phase of illness revealed abnormalities of one or more sinuses in 27 (87%) of 31 young adults.[27] Without antibiotic therapy, there was complete resolution or marked improvement of the sinus abnormalities in 11 (79%) of the 14 subjects for whom second CT scans were obtained 2 weeks later. In another study, MRI revealed that 60% of children with URIs had major abnormalities in their paranasal sinuses, which tended to resolve without antibiotic therapy.[28] It is not known whether sinus abnormalities result from viral infection of the sinus mucosa or from impaired sinus drainage due to viral rhinitis. Nose blowing can generate enough pressure to force fluid from the nasopharynx into the paranasal sinuses, suggesting that nose blowing may force mucus containing viruses, bacteria, and inflammatory mediators into the paranasal sinuses during a cold.[29]

The middle ear can be involved during uncomplicated colds. Studies have shown that two thirds of school-aged children develop abnormal middle ear pressures within 2 weeks after the onset of a cold.[30] Otitis media was not diagnosed during the study because ears were not examined, and none of the children sought medical care. It is not known whether the abnormal middle ear pressures result from viral infection of the mucosa of the middle ear and eustachian tube or from viral nasopharyngitis with secondary eustachian tube dysfunction.

Clinical Manifestations

Symptoms of the common cold do not vary by specific causative virus. In older children and adults, rhinorrhea, nasal obstruction, and sore or scratchy throat are typical. The rhinorrhea is initially clear but may become colored as the illness proceeds, and patients can cough or sneeze. Fever (>38°C) is uncommon in adults. Other symptoms are malaise, sinus fullness, and hoarseness. Objective findings are minimal except for mild erythema of the nasal mucosa or pharynx. Symptoms resolve in 5 to 7 days.

Compared with adults, infants and preschool children with colds are more likely to have fever (>38°C) and moderate enlargement of the anterior cervical lymph nodes (Table 26.2).[1] Rhinorrhea may not be noticed until the nasal discharge becomes colored. Nasal congestion can disrupt sleep and lead to fatigue and irritability. The illness often persists in infants and preschool children for 10 to 14 days.[31]

TABLE 26.2

Characteristics of Viral Colds in Adults and Young Children

Characteristic	**Adults**	**Children <6 Years**
Frequency	2–4 per year	One per month, September–April
Fever	Rare	Common during first 3 days
Nasal manifestations	Congestion	Colored nasal discharge
Duration of illness	5–7 days	14 days

Modified from Hendley JO. Epidemiology, pathogenesis, and treatment of the common cold. Semin Pediatr Infect Dis 1998;9:50–55.

Differential Diagnosis

The differential diagnoses of a cold include allergic rhinitis, vasomotor rhinitis, intranasal foreign body, and sinusitis. A diagnosis of allergic rhinitis is suggested by a seasonal pattern of clear rhinorrhea, absence of associated fever, and family history of allergy. Possible associated conditions are asthma and eczema. Physical findings consistent with allergic rhinitis include allergic shiners (i.e., dark circles under the eyes) and nasal salute (i.e., wiping or rubbing the nose with a transverse or upward movement of the hand).

Detection of numerous eosinophils on microscopic examination of the nasal mucus using Hansel stain confirms the diagnosis of allergic rhinitis. A diagnosis of vasomotor rhinitis is suggested by a chronic course without fever or sore throat. The diagnosis of bacterial sinusitis is suggested by persistent rhinorrhea or cough, or both, for more than 10 days.[32]

Clinical Approach

The diagnosis of a cold is based on history and physical examination; typically, laboratory tests are not useful. The rapid test for detecting RSV, influenza, parainfluenza, and adenovirus antigens in nasal secretions can be used to confirm the diagnosis. RSV, rhinovirus, influenza viruses, parainfluenza viruses, and adenoviruses also can be isolated in cell culture. Because HCoVs cannot be detected reliably in cell culture, a serologic titer elevation can be used for diagnosis if necessary.

PCR assays for detection of all the respiratory viruses are available increasingly in clinical laboratories, but there is a lack of standardization and validation for many of the tests offered.

Meaningful interpretation of PCR results remains challenging because PCR detection of virus can occur in several clinical scenarios, including coinfection with multiple viruses, viral detection during the incubation period, subclinical infection, infection with the identified virus, variable duration of viral shedding, and sequential infection with different serotypes of the same species.[33] Other methods of detection can be used but are rarely needed.

Management

No antiviral agents are available that are effective for treatment of the common cold. Although an array of medications may be used to relieve symptoms, there is little scientific evidence to support the use of symptomatic treatments in children. Because the common cold is a self-limited illness with symptomatology that is largely subjective, a substantial placebo effect can suggest that various treatments have some efficacy. Inadequate blinding of placebo recipients in a study can make an ineffective treatment appear effective.

In adults with colds, first-generation antihistamines (e.g., chlorpheniramine) have been shown to provide modest symptomatic relief, with decreases in nasal discharge, sneezing, nose blowing, and duration of symptoms,[34] presumably because of the anticholinergic effects of these medications. A randomized, double-blind, placebo-controlled study of preschool children with URIs showed that treatment with an antihistamine-decongestant combination (i.e., brompheniramine maleate and phenylpropanolamine hydrochloride) produced no improvement in cough, rhinorrhea, or nasal congestion, although a larger proportion of the treated children (47% vs. 26%) were asleep 2 hours after treatment.[35]

Numerous decongestants, antitussives, and expectorants are available over the counter, but there is no evidence to support their use in children. A study of phenylephrine, a topical decongestant, for the treatment children 6 to 18 months old showed no decrease in nasal obstruction with its use during a URI.[36] In a study comparing placebo, dextromethorphan, and codeine for cough suppression in children 18 months to 12 years old, cough decreased in all patients within 3 days, but there was no difference in cough reduction among the three treatment groups.[37] Guaifenesin, an expectorant, has not been shown to change the volume or quality of sputum or the frequency of cough in young adults with colds.[38] Echinacea preparations, often thought to be effective in the treatment of the common cold, have no effect on the prevention or treatment of rhinovirus infection.[39] Similarly, intranasal zinc gluconate has had no effect for the treatment of colds[40] or prevention of experimental rhinovirus colds.[41] In January, 2008, the US Food and Drug Administration issued an advisory strongly recommending that over-the-counter cold and cough medications not be given to infants because of the risk of life-threatening side effects.

Antibiotics have no role in the treatment of uncomplicated URIs in children. Antibiotic therapy does not hasten resolution of the viral infection or reduce the likelihood of occurrence of secondary bacterial infection.[42] Antibiotics are indicated only in cases of secondary bacterial infection, such as sinusitis and acute otitis media.

Supportive measures remain the mainstay of treatment for the common cold in children. Bulb suction with saline drops (i.e., ≈1 teaspoon of salt in 2 cups of water) may help relieve nasal congestion and remove secretions. One study suggests that honey given at bedtime may help reduce cough in children with URIs, although honey is not recommended for children younger than 12 months because of the risk of exposure to *Clostridium botulinum* spores.[43] Vapor rub applied to the chest and neck of children between the ages of 2 and 11 years may help reduce nighttime cough.[44]

Complications

The common cold usually resolves in about 10 to 14 days in infants and children. New-onset fever and earache during this period may herald the development of bacterial otitis media, which occurs in about 5% of colds in preschool children. Persistence of nasal symptoms for longer than 10 days was thought to signify the development of a secondary bacterial sinusitis, but a study found that 20 children hospitalized for preseptal or orbital cellulitis, indicative of bacterial sinusitis, had symptoms of acute respiratory tract infection for 7 or fewer days before hospitalization, suggesting that the complications of rhinosinusitis can occur during the first few days of a cold.[45]

Bacterial pneumonia is an uncommon secondary infection. For children with underlying reactive airways disease, wheezing is common during the course of a viral URI; at least 50% of asthma exacerbations in children are associated with viral infection. Children who experience more than one *lower* respiratory tract infection (e.g., croup, bronchiolitis) during their first year of life have an increased risk of asthma thereafter.[46] Other complications are epistaxis, eustachian tube dysfunction, conjunctivitis, and pharyngitis.

Recent Advances

Symptoms of the common cold appear to result from the effects of inflammatory mediators released in response to the viral infection of the respiratory tract. As the determinants of this process are further elucidated, treatments may be developed that can interrupt or ameliorate release of inflammatory mediators and prevent or reduce the symptoms of the common cold. Vaccines are unlikely to be useful for prevention because of the large number of serotypes of some cold viruses and the lack of lasting immunity to others.

The use of alcohol-based hand gels has been suggested as a means of reducing secondary transmission of respiratory illnesses in the home,[47] but this approach was not shown to be effective in one field trial.[48] Virucidal tissues have been effective in preventing viral passage and transmission and may reduce secondary transmission by about 30%.[49,50] Until new methods are developed, prevention of the common cold is limited to avoiding self-inoculation (i.e., transfer of virus from contaminated fingers to nasal or conjunctival mucosa) by removing virus through handwashing or by killing virus with application of a virucide to the hands.

Pharyngitis

John C. Arnold, Victor Nizet

Acute pharyngitis is one of the most common illnesses for which children in the United States visit primary care providers. The diagnoses of acute pharyngitis, acute tonsillitis, or "strep throat" are made more than 12 million times annually.[1,2]

Table 27.1 provides a partial list of etiologic agents for acute pharyngitis. Most cases in children and adolescents are caused by viruses and are benign and self-limited. Group A β-hemolytic *Streptococcus* (GAS) (e.g., *Streptococcus pyogenes*) is the most important bacterial cause. Strategies for the diagnosis and treatment of pharyngitis in children and adolescents depend on differentiating the large group of patients with viral pharyngitis who cannot benefit from antimicrobial therapy from the small group of patients with GAS pharyngitis who can. Distinguishing between groups is important to minimize the unnecessary use of antibiotics in children and adolescents while diagnosing and treating patients for whom benefit is likely.

TABLE 27.1

Causes of Acute Pharyngitis

Etiologic Agents	Associated Disorders or Clinical Findings
BACTERIAL	
Group A *Streptococcus*	Scarlet fever
Groups C and G streptococci	
Mixed anaerobes	Vincent angina
Neisseria gonorrhoeae	
Corynebacterium diphtheriae	Diphtheria
Arcanobacterium haemolyticum	Scarlatiniform rash

Yersinia enterocolitica	Enterocolitis
Yersinia pestis	Plague
Francisella tularensis	Tularemia
Fusobacterium necrophorum	Lemierre syndrome (jugular vein septic thrombophlebitis)
VIRAL	
Rhinovirus	Common cold
Coronavirus	Common cold
Adenovirus	Pharyngoconjunctival fever; acute respiratory disease
Herpes simplex virus types 1 and 2	Gingivostomatitis
Parainfluenza virus	Common cold; croup
Coxsackievirus A	Herpangina; hand-foot-mouth disease
Epstein-Barr virus	Infectious mononucleosis
Cytomegalovirus	Cytomegalovirus mononucleosis
Human immunodeficiency virus (HIV)	Primary HIV infection
MYCOPLASMAL	
Mycoplasma pneumoniae	Acute respiratory disease; pneumonia
CHLAMYDIAL	
Chlamydophila psittaci	Acute respiratory disease; pneumonia
Chlamydophila pneumoniae	Pneumonia
NONINFECTIOUS CAUSES	
Gastroesophageal reflux disease	Heartburn
Laryngopharyngeal reflux	Cough, hoarseness
PFAPA syndrome	Periodic fever, aphthous ulcers, adenitis
Allergic pharyngitis	Scratchy sensation, postnasal drip, hoarseness
Kawasaki disease	Other typical findings (extremity changes, conjunctivitis)

HIV, Human immunodeficiency virus; PFAPA, periodic fever, aphthous stomatitis, pharyngitis, and cervical adenitis.

Modified from Bisno AL, Gerber MA, Gwaltney JM, et al. Practice guideline for the diagnosis and management of group A streptococcal pharyngitis. Clin Infect Dis 2002;35:113–125.

Etiology

Viruses are the most common cause of acute pharyngitis in children and adolescents. Respiratory viruses (e.g., influenza virus, parainfluenza virus, rhinovirus, coronavirus, adenovirus, human metapneumovirus, respiratory syncytial virus), enteroviruses (e.g., coxsackievirus, echovirus), herpes simplex virus (HSV), and Epstein-Barr virus (EBV) are frequent causes of pharyngitis. EBV pharyngitis often is accompanied by other clinical findings of infectious mononucleosis (e.g., generalized lymphadenopathy, splenomegaly) and can be exudative and indistinguishable from GAS pharyngitis. HSV pharyngitis often is associated with stomatitis in children and tends to affect the anterior oral mucosa, including the gingiva, buccal mucosa, and tongue. Enteroviral pharyngitis can be an isolated finding (e.g., herpangina) or part of the syndrome of hand-foot-and-mouth disease, and it has a typical appearance. Systemic infections with other viruses (e.g., cytomegalovirus, rubella virus, measles virus) can include pharyngitis.

GAS is the most commonly identified bacterial cause of acute pharyngitis, accounting for 15% to 30% of pediatric pharyngitis. *Fusobacterium necrophorum,* the typical etiologic agent of Lemierre syndrome, is an increasingly reported cause of uncomplicated pharyngitis, especially in older children and young adults.[3,4] Other causes include groups C and G β-hemolytic streptococci (GCS and GGS, respectively). *Arcanobacterium haemolyticum* is a rare cause in adolescents, and *Neisseria gonorrhoeae* can cause acute pharyngitis in sexually active adolescents. Other bacteria such as *Francisella tularensis, Yersinia enterocolitica,* and *Corynebacterium diphtheriae* and mixed infections with anaerobic bacteria (e.g., Vincent angina) are rare causes.

Chlamydophila pneumoniae and *Mycoplasma pneumoniae* have been implicated rarely, particularly in adults. Although bacteria such as *Staphylococcus aureus, Haemophilus influenzae,* and *Streptococcus pneumoniae* frequently are isolated from throat cultures of children and adolescents with acute pharyngitis, their etiologic role is not established. Noninfectious cases of recurrent or prolonged pharyngitis and sore throat include the periodic fever, adenitis, pharyngitis, and aphthous ulcers (PFAPA) syndrome; gastroesophageal or laryngopharyngeal reflux; and allergic rhinitis.

Epidemiology

Most cases of acute pharyngitis occur during the colder months of the year, when respiratory viruses are prevalent. Spread among family members in the home is a prominent feature of the epidemiology of most agents, with children providing the major reservoir. GAS pharyngitis is primarily a disease of children 5 to 15 years of age, and in temperate climates, the prevalence is highest in winter and early spring. Enteroviral pharyngitis typically occurs in the summer and early fall.

Gonococcal pharyngitis occurs in sexually active adolescents and young adults. The usual mode of infection is through orogenital sexual contact. Sexual abuse must be considered strongly when *N. gonorrhoeae* is isolated from the pharynx of a prepubertal child. Widespread immunization with diphtheria toxoid has made diphtheria a rare disease in the United States, with fewer than 5 cases reported annually.

GCS and GGS express many of the same toxins as GAS, including streptolysin S and O. GCS pharyngitis can have clinical features similar to GAS and can cause elevated levels of serum antistreptolysin O (ASO) antibody.[5] GCS is a relatively common cause of acute pharyngitis among college students and adults who seek urgent care.[6,7] Outbreaks of GCS pharyngitis related to consumption of contaminated food products (e.g., unpasteurized cow milk) have been reported in families and schools.[8] Although there also are several well-documented foodborne outbreaks of GGS pharyngitis, the role of GGS in acute, endemic pharyngitis remains unclear. A community-wide outbreak of pharyngitis among children was described in which GGS was isolated from 25% of 222 consecutive children with acute pharyngitis seen in a private pediatric office. Results of DNA fingerprinting suggested that 75% of isolates belonged to the same GGS clone.[9]

The role of GCS and GGS in acute pharyngitis may be underestimated, and many laboratories do not report GCS or GGS even when the organisms are identified in throat cultures. Laboratories may use bacitracin susceptibility to identify GAS; many GCS and GGS are bacitracin resistant. Rapid antigen detection tests (RADTs) recognize the cell wall carbohydrate of GAS but are nonreactive with the carbohydrates of GCS or GGS.[10]

Clinical Manifestations

Group A *Streptococcus*

Certain clinical and epidemiologic findings suggest GAS as the cause of acute pharyngitis (Box 27.1). Patients with GAS pharyngitis commonly have sore throat (usually of sudden onset), severe pain on swallowing, and fever. They also can have headache, nausea, vomiting, and abdominal pain. Examination typically reveals tonsillopharyngeal erythema with or without exudates and tender, enlarged anterior cervical lymph nodes. Other findings can include a beefy, red, swollen uvula; petechiae on the palate; and a scarlatiniform rash. No finding is specific for GAS.

Box 27.1

Clinical and Epidemiologic Characteristics of Group A β-Hemolytic Streptococcal and Viral Pharyngitis

Features Suggesting Group A β-Hemolytic Streptococcus

- Sudden onset
- Sore throat
- Fever
- Scarlet fever rash
- Headache
- Nausea, vomiting, and abdominal pain
- Inflammation of pharynx and tonsils
- Patchy discrete tonsillar exudates
- Tender, enlarged anterior cervical nodes
- Patient 5–15 years of age
- Presentation in winter or early spring
- History of exposure

Features Suggesting Viruses

- Conjunctivitis
- Coryza
- Cough

- Hoarseness
- Myalgia
- Diarrhea
- Characteristic exanthems

Modified from Bisno AL, Gerber MA, Gwaltney JM, et al. Practice guideline for the diagnosis and management of group A streptococcal pharyngitis. Clin Infect Dis 2002;35:113–125.

Many patients with GAS pharyngitis exhibit signs and symptoms that are milder than the classic presentation of illness. Some have bona fide GAS infection (i.e., elevated titers of ASO antibodies), whereas others are merely colonized and have an intercurrent viral infection. GAS naso-pharyngitis in infants (i.e., streptococcosis) is uncommon, and it is difficult to differentiate from viral infections because GAS nasopharyngitis can cause purulent nasal discharge and excoriated nares, and infection can occur without pharyngitis.

Scarlet fever is associated with a characteristic rash that is caused by GAS that produce a pyrogenic exotoxin (i.e., erythrogenic toxin). Scarlet fever occurs in people who lack antitoxin antibodies. Although less common and clinically less severe than in the past, the incidence of scarlet fever is cyclical, depending on the prevalence of toxin-producing strains of GAS and the immune status of the population. The modes of transmission, age distribution, and other epidemiologic features are otherwise similar to those of GAS pharyngitis.

The rash of scarlet fever appears within 24 to 48 hours of the onset of signs and symptoms and can be the first sign. The rash often begins around the neck and spreads over the trunk and extremities. It is a diffuse, finely papular (sandpaper-like), erythematous eruption that produces bright red discoloration of the skin that blanches with pressure. Involvement often is more intense along the creases in the antecubital area, axillae, and groin, and petechiae can occur along the creases (i.e., Pastia lines). The face usually is spared, although the cheeks can be erythematous with pallor around the mouth (Fig. 27.1). After 3 to 4 days, the rash begins to fade and is followed by fine desquamation, first on the face and progressing downward. Occasionally, sheet-like desquamation occurs around the fingernails periungually, the palms, and the soles. Pharyngeal findings are the same as with GAS pharyngitis. The tongue usually is coated, and the papillae are swollen. With desquamation, the reddened papillae are prominent, giving the tongue a strawberry appearance.

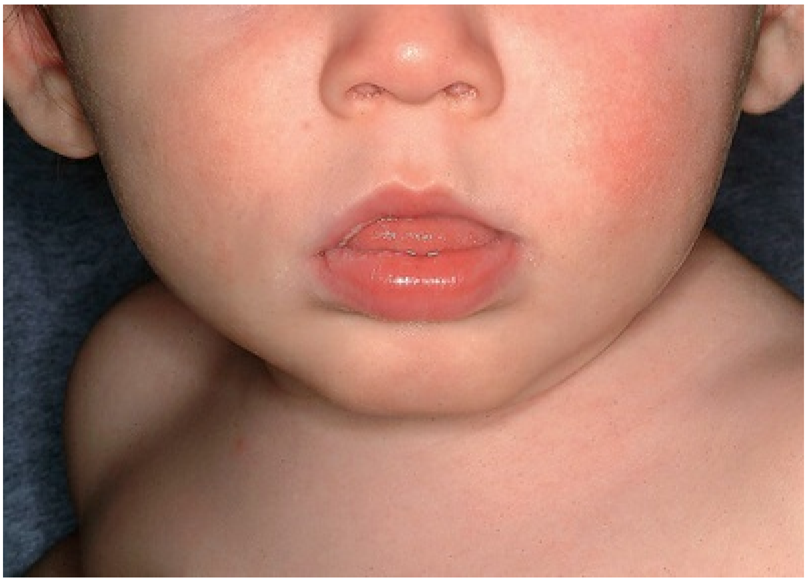

FIGURE 27.1 The child has group A streptococcal pharyngitis and scarlatiniform rash, with characteristic circumoral pallor. (Courtesy of J.H. Brien ©.)

There can be substantial overlap between the findings of scarlet fever and Kawasaki disease. Lack of response to antibiotic therapy for suspected scarlet fever should prompt consideration of Kawasaki disease.

Viruses

Clinical findings such as conjunctivitis, cough, hoarseness, coryza, anterior stomatitis, discrete ulcerative lesions, viral exanthema, myalgia, and diarrhea suggest a virus rather than GAS as the cause of acute pharyngitis (see Box 27.1).

Adenovirus pharyngitis typically is associated with fever, erythema of the pharynx, enlarged tonsils with exudate, and enlarged cervical lymph nodes. Adenoviral pharyngitis can be associated with conjunctivitis, which is referred to as *pharyngoconjunctival fever*. Adenovirus pharyngitis can persist for up to 7 days and conjunctivitis up to 14 days, after which both resolve spontaneously. Outbreaks of pharyngoconjunctival fever have been associated with transmission in swimming pools. Widespread epidemics and sporadic cases also occur.

Enteroviruses (i.e., coxsackievirus, echovirus, and enteroviruses) are associated with erythematous pharyngitis, but tonsillar exudate and cervical lymphadenopathy are unusual. Fever can be prominent. Resolution usually occurs within a few days. Herpangina is a specific syndrome caused by coxsackieviruses A or B or echoviruses. It is characterized by fever and painful, discrete, grey-white papulovesicular or ulcerative lesions on an erythematous base in the posterior oropharynx (Fig. 27.2). Hand-foot-and-mouth disease is characterized by painful vesicles and ulcers throughout the oropharynx associated with vesicles on the palms, soles, and sometimes on the trunk or extremities. Enteroviral lesions usually resolve within 7 days.

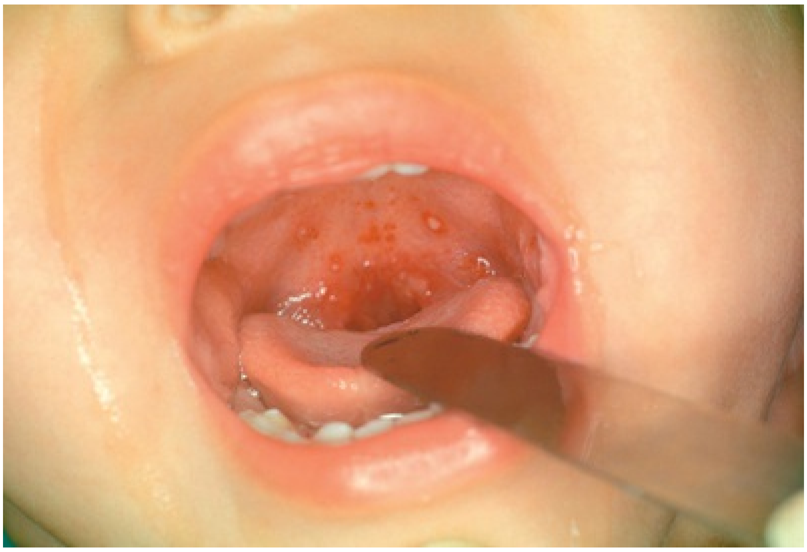

FIGURE 27.2 The child has posterior pharyngeal, grey-white, papulovesicular lesions characteristic of enteroviral herpangina. (Courtesy of J.H. Brien ©.)

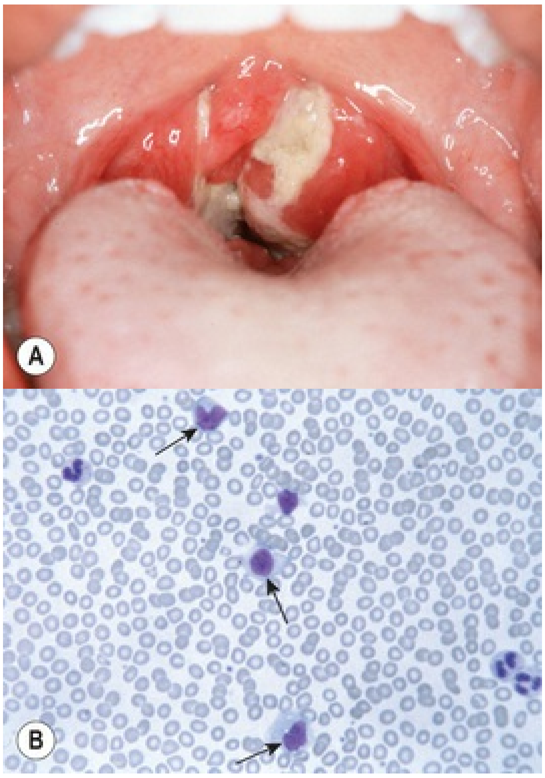
Primary oral HSV infections usually occur in young children and typically produce acute gingivostomatitis associated with ulcerating vesicular lesions throughout the anterior mouth and lips, sparing the posterior pharynx. HSV gingivostomatitis can last up to 2 weeks and often is associated with high fever. Pain can be intense, and poor oral intake can lead to dehydration. In adolescents and adults, HSV also can cause mild pharyngitis that may or may not be associated with typical vesicular, ulcerating lesions.

EBV pharyngitis during infectious mononucleosis can be severe, with oral clinical findings identical to those of GAS pharyngitis (Fig. 27.3A). Generalized lymphadenopathy and hepatosplenomegaly also can occur. Posterior cervical lymphadenopathy and presternal and periorbital edema are distinctive findings. Fever and pharyngitis typically last 1 to 3 weeks, whereas the lymphadenopathy and hepatosplenomegaly resolve over 3 to 6 weeks. Laboratory findings include atypical lymphocytosis (see Fig. 27.3B), heterophile antibodies, viremia (detected by polymerase chain reaction [PCR] methods), and specific antibodies to EBV antigens. If amoxicillin has been given, an intense maculopapular rash often occurs (see Fig. 27.3C).



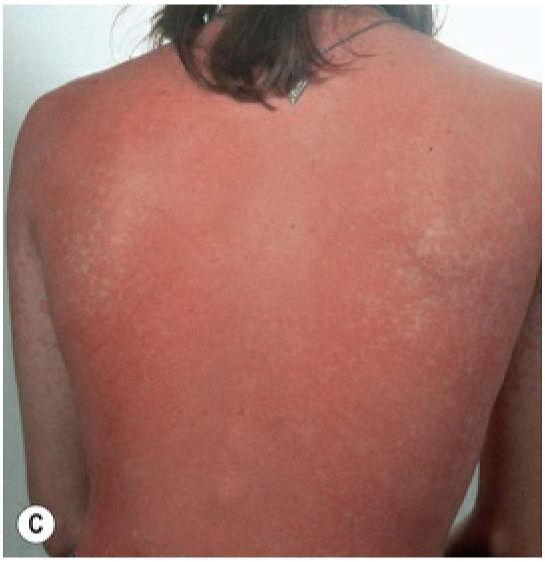


FIGURE 27.3 (A) Pharyngeal erythema and exudate due to Epstein-Barr virus (EBV) infection. (B) Peripheral blood smear shows atypical lymphocytes *(arrows)* in a patient with EBV mononucleosis. Notice the abundant cytoplasm with vacuoles and deformation of cell by surrounding cells. (C) Diffuse. erythematous. raised rash on an adolescent with EBV mononucleosis who received amoxicillin. Notice the predominance of exanthem on the trunk and coalescence of lesions.

Other Bacteria

A. haemolyticum pharyngitis can resemble GAS pharyngitis, including a scarlatiniform rash. Rarely, *A. haemolyticum* can produce a membranous pharyngitis that can be confused with diphtheria.

Pharyngeal diphtheria is characterized by a greyish brown pseudomembrane that can be limited to one or both tonsils or can extend widely to involve the nares, uvula, soft palate, pharynx, larynx, and tracheobronchial tree. Involvement of the tracheobronchial tree can lead to life-threatening respiratory obstruction. Soft tissue edema and prominent cervical and submental lymphadenopathy can cause a bull-neck appearance.

F. necrophorum can be the cause of pharyngitis in 10% to 20% of adolescents and young adults.[3,11,12] *F. necrophorum* appears to cause the typical signs of bacterial pharyngitis (i.e., high fever, odynophagia, lymphadenopathy, and exudative tonsillitis) and can cause concomitant bacteremia.[13] The frequency of progression from tonsillitis to Lemierre syndrome is unknown.

Diagnosis

Distinguishing between GAS and viral pharyngitis is key to management in US practice. Scoring systems that incorporate clinical and epidemiologic features attempt to predict the probability that the illness is caused by GAS.[14,15] Clinical scoring systems are best aimed to identify individuals at such low risk of GAS infection that a throat culture or RADT usually is unnecessary. In a 2012 systematic review of 34 articles with individual symptoms and signs of pharyngitis assessed and 15 articles with data on prediction rules, no individual or combined symptoms or signs allowed formation of guidelines that could be used to diagnose GAS pharyngitis with a probability of 85% or higher.[16] Similarly, a 2015 review found a range of probability from 64% to 87%. The guidelines from the Infectious Diseases Society of America (IDSA),[17] the American Academy of Pediatrics (AAP),[18] and the American Heart Association (AHA)[19] require microbiologic confirmation with a throat culture or RADT for the diagnosis of GAS pharyngitis.

The decision to perform a microbiologic test on a child or adolescent with acute pharyngitis should be based on the clinical and epidemiologic characteristics of the illness (see Box 27.1). A history of close contact with a documented case of GAS pharyngitis or high prevalence of GAS in the community also can be helpful. More selective use of diagnostic studies for GAS can increase the proportion of positive test results and the tests' positive predictive value (i.e., percentage of patients with positive tests who are infected rather than merely colonized with GAS).

Because adults infrequently are infected with GAS and rarely develop rheumatic fever, in 2001, the Centers for Disease Control and Prevention (CDC), American Academy of Family Physicians (AAFP), and the American College of Physicians with the American Society of Internal Medicine (ACP-ASIM) recommended the use of a clinical algorithm without microbiologic confirmation as an acceptable approach to the diagnosis of GAS pharyngitis in adults only.[20] Although the goal of this algorithm-based strategy was to reduce the inappropriate use of antibiotics, a study intended to assess the impact of six different guidelines on the identification and treatment of GAS pharyngitis in children and adults[21] found that selective use of RADTs with or without throat culture and treatment based only on positive test results significantly reduced the inappropriate use of antibiotics in adults. In contrast, the empiric strategy proposed in the CDC, AAFP, and ACP-ASIM guidelines resulted in the administration of unnecessary antibiotics to an unacceptably large number of adults. Diagnosis of adults only by symptom complex therefore has been discouraged in the latest AHA scientific statement.[19] The ACP-ASIM guideline has been inactivated, and the CDC now recommends diagnostic testing for adults who have symptoms consistent with GAS pharyngitis.[22]

Throat Culture

Culture on sheep blood agar of a specimen obtained by throat swab is the standard laboratory procedure for the microbiologic confirmation of GAS pharyngitis.[23] If performed correctly, a throat culture has a sensitivity of 90% to 95%.[24] A negative result can occur if the patient has received an antibiotic before sampling.

Several variables affect the accuracy of throat culture results. One of the most important is the manner in which the specimen is obtained.[25,26] The surface of both tonsils or tonsillar fossae and the posterior pharyngeal wall should be swabbed. Other areas of the pharynx and mouth (e.g., anterior mucosa, tongue, saliva) are not acceptable sampling sites and should not be touched during the procedure.

Anaerobic incubation and the use of selective culture media can increase the sensitivity of throat cultures for GAS recovery.[27,28] However, data regarding the impact of the atmosphere of incubation and the culture media are conflicting, and in the absence of definite benefit, the increased cost and effort associated with anaerobic incubation and selective culture media are difficult to justify.[28–31]

Duration of incubation can impact the yield of throat cultures. Cultures should be incubated at 35°C to 37°C for at least 18 to 24 hours before reading. Additional overnight incubation at room temperature, however, identifies substantially more positive cultures. In a study of patients with pharyngitis and negative RADT results, 40% of positive GAS cultures were negative after 24 hours of incubation but positive after 48 hours.[32] Although initial therapeutic decisions can be guided by negative results at 24 hours, it is advisable to wait 48 hours for definitive results.

The clinical significance of the number of colonies of GAS growing on inoculated agar is controversial. Although the density of bacteria is likely to be greater for patients with bona fide acute GAS pharyngitis than for GAS carriers, there is too much overlap in the colony counts to permit differentiation on the basis of colony density.[29]

The bacitracin disk test is the most widely used direct microbiologic method for the differentiation of GAS from other β-hemolytic streptococci using growth on sheep blood agar. Presumptive identification is based on the observation that more than 95% of GAS demonstrate a zone of inhibition around a disk containing 0.04 units of bacitracin, whereas 83% to 97% of non-GAS are not inhibited by bacitracin.[29] An alternative and highly specific method for the differentiation of β-hemolytic streptococci is a commercially available, group-specific cell wall carbohydrate antigen detection test applied directly to isolated colonies. Additional expense for the minimal improvement in accuracy may not be justified.[29]

Rapid Antigen Detection Tests and Nucleic Acid Detection

RADTs developed for the identification of GAS directly from throat swabs are more expensive than blood agar cultures, but they offer speed in providing results. Rapid identification and treatment of patients with GAS pharyngitis can reduce the risk of the spread of GAS, speed clinical improvement, and allow the patient to return to school or work sooner.[24,33] In certain environments (e.g., emergency departments), the use of RADTs compared with throat cultures significantly increased the number of patients appropriately treated for GAS pharyngitis.[34,35]

Most RADTs have specificities of 95% or higher compared with blood agar cultures.[36] Therapeutic decisions can be made with confidence on the basis of a positive RADT result. However, the sensitivity of RADTs is between 70% and 90%.[36] Two large meta-analyses, which pooled 55,766 and 23,934 patients, concluded that modern RADTs had a sensitivity in children of 86%.[37,38] Although some patients with positive RADT results merely are GAS carriers, a large proportion are infected with GAS.[39]

The first RADTs used latex agglutination methodology, were relatively insensitive, and had unclear end points.[36] Subsequent tests based on enzyme immunoassay techniques had a more sharply defined end point and increased sensitivity. RADTs using optical immunoassay (OIA), bead concentration of antigens and fluorescent detection, and chemiluminescent DNA probes may be more sensitive than other RADTs, perhaps as sensitive as blood agar plate cultures,[36,40] but because most rapid detection is done by RADTs with marginal sensitivity, advisory groups still recommend a confirmatory blood agar culture for children and adolescents who are suspected on clinical grounds of having GAS pharyngitis and have a negative RADT result. Because of the higher sensitivity of RADTs for adults than children,[38] the IDSA allows for an exclusion of GAS pharyngitis based on a negative RADT result alone, although physicians may continue to use throat culture to achieve maximal sensitivity.[17]

Although nucleic acid detection has superior sensitivity compared with RADT and has sensitivity similar to culture in most circumstances,[41,42] clinical results may not be faster than culture. Although faster technologies are becoming available, with nucleic acid detection in 8 minutes in point-of-care tests,[43] the high cost of new technologies may limit their practical use in primary care settings.

Culture, RADT, and nucleic acid amplification tests cannot accurately differentiate individuals with GAS pharyngitis from carriers. However, definitive testing facilitates nontreatment of most patients (i.e., those without GAS). An estimated 12 to 15 million provider visits for sore throat occur each year in the United States. Antimicrobial therapy historically was prescribed at 60% to 73% of these visits.[2,44] Education can reduce the prescription of antibiotics for children and adolescents with pharyngitis.[45,46] One study documented an overall decrease in prescriptions for children with pharyngitis from 65% in 1998 to 56% in 2010, although the decrease in penicillin prescriptions was offset by an increase in macrolide prescriptions.[2]

Follow-Up Testing

Most asymptomatic people who have a positive throat culture or RADT result after completing a course of appropriate antimicrobial therapy for GAS pharyngitis are GAS carriers,[47] and routine follow-up testing is not indicated. Follow-up throat culture or RADT for asymptomatic individuals should be performed only for those with a history of rheumatic fever and should be considered in patients who develop acute pharyngitis during outbreaks of acute rheumatic fever or poststreptococcal acute glomerulonephritis and for individuals in closed or semiclosed communities during outbreaks of GAS pharyngitis.[47]

Other Diagnostic Considerations

Antistreptococcal antibody titers have no value in the diagnosis of acute GAS pharyngitis, but they are useful in prospective epidemiologic studies to differentiate true GAS infections from GAS carriage. Antistreptococcal antibodies are valuable for confirmation of prior GAS infection in patients suspected of having acute rheumatic fever or other nonsuppurative complications.

The need to definitively diagnose non-GAS causes of pharyngitis occurs rarely and usually only in those who are very ill or have prolonged symptoms. *A. haemolyticum* is not identified using standard culture methods intended to identify only GAS and requires the use of standard respiratory culture methods. *N. gonorrhoeae* can be identified by using selective agar growth media or nucleic acid amplification tests. EBV is routinely diagnosed using the heterophile antibody (i.e., monospot), but low sensitivity in younger children necessitates the use of specific antibody testing or serum PCR methods. Other common viruses such as HSV, adenoviruses, and enteroviruses can be identified in general viral cultures or by PCR, or both.

Pursuit of diagnosis of *F. necrophorum* pharyngitis is controversial.[3] Isolation of this anaerobe requires special laboratory techniques, or detection requires use of molecular techniques. There are no data that treatment of *F. necrophorum* pharyngitis hastens symptomatic relief or prevents Lemierre disease.

Treatment

Antimicrobial therapy is indicated for individuals with symptomatic pharyngitis when GAS is confirmed by RADT or culture.[17] When the clinical and epidemiologic findings strongly suggest GAS, antimicrobial therapy can be initiated while awaiting microbiologic confirmation, provided that therapy is discontinued if the RADT result or culture is negative.

Antimicrobial therapy for GAS pharyngitis shortens the clinical course of the illness.[33] However, GAS pharyngitis usually is self-limited, and most signs and symptoms resolve spontaneously within 3 or 4 days of onset.[48] Initiation of antimicrobial therapy can be delayed for up to 9 days after the onset of GAS pharyngitis and still prevent the occurrence of acute rheumatic fever.[49]

Antimicrobial Agents

Penicillin and its congeners (e.g., ampicillin, amoxicillin) and numerous cephalosporins, macrolides, and clindamycin are effective treatment for GAS pharyngitis. Several advisory groups have recommended penicillin as the treatment of choice.[17,18] GAS has remained exquisitely susceptible to β-lactam agents over 5 decades.[17,18,50] Amoxicillin often is used because of the acceptable taste of the suspension, although efficacy appears to equal penicillin. Orally administered clarithromycin and azithromycin also are effective (discussed later). Sulfa drugs, including trimethoprim-sulfamethoxazole, and tetracyclines are not effective and should not be used to treat GAS pharyngitis.

On the basis of a meta-analysis of 35 clinical trials completed between 1970 and 1999 in which a cephalosporin was compared with penicillin for the treatment of GAS tonsillopharyngitis, authors concluded that cephalosporins should be the treatment of choice for GAS tonsillopharyngitis.[51] However, several methodologic flaws (notably the inclusion of GAS carriers) led to controversy regarding this conclusion.[52] Indirect evidence of the superiority of cephalosporins over penicillins to prevent treatment failures and relapses continues to appear.[53–55] However, there has not been a prospective study to clarify the issue beyond doubt, and eradication of the carrier state confounds many studies. Although the use of cephalosporins for GAS pharyngitis could reduce the number of people (especially chronic carriers) who harbor GAS after completing therapy, empiric first-line use would be associated with substantial economic cost and risk for increased antimicrobial resistance without substantial benefit. There are compelling reasons (e.g., narrow antimicrobial spectrum, low cost, impressive safety profile) to continue to use penicillin as the drug of choice for uncomplicated GAS pharyngitis.

Dosing Intervals and Duration of Therapy

Oral penicillin must be administered many times each day for 10 days to achieve maximal rates of GAS eradication. Attempts to treat GAS pharyngitis with a single daily dose of penicillin have been unsuccessful.[56] Reduced frequency of dosing and shorter treatment courses (<10 days) may result in better patient adherence to therapy. Several antimicrobial agents, including clarithromycin, cefuroxime, cefixime, ceftibuten, cefdinir, and cefpodoxime, are effective in GAS eradication when administered for 5 days or less,[57–62] and effective eradication with once-daily dosing has been described for amoxicillin, azithromycin, cefadroxil, cefixime, ceftibuten, cefpodoxime, cefprozil, and cefdinir.[18,58,61,63–66]

However, the end points of these studies typically are eradication of GAS, not symptomatic improvement or prevention of rheumatic fever, which are the two main clinical reasons for treatment. Many agents have a broader spectrum of activity and, even when administered for short courses, can be more expensive than standard therapy.[58] Additional studies are needed before these short-course or once-daily dosing regimens can be recommended routinely over penicillin.

Table 27.2 gives recommendations for several regimens with proven efficacy for GAS pharyngitis.[14,18] Intramuscular benzathine penicillin G is preferred in patients unlikely to complete a full 10-day course of oral therapy.

TABLE 27.2

Antimicrobial Therapy for Group A β-Hemolytic Streptococcal Pharyngitis

Antimicrobial Agent	Dosage	Duration
ORAL ADMINISTRATION		
Penicillin	Children: 250 mg bid or tid	10 days
	Adolescents and adults: 250 mg tid or qid	10 day
	Adolescents and adults: 500 mg bid	10 days
Erythromycin[a]	Varies with formulation	10 days
First-generation cephalosporins[a,b]	Varies with agent	10 days
INTRAMUSCULAR ADMINISTRATION		
Benzathine penicillin G	600,000 U (for patients ≤27 kg)	1 dose
	1.2 million U (for patients >27 kg)	1 dose
Mixtures of benzathine and procaine penicillin G	Varies with formulation[c]	—

[a] For patients allergic to penicillin.

[b] These agents should not be used to treat patients with immediate-type hypersensitivity to β-lactam antibiotics.

[c] Dose should be determined on basis of benzathine component.

bid, Twice daily; *qid*, four times daily; *tid*, three times daily.

Macrolide and Lincosamide Resistance

Although GAS resistance to penicillin has not occurred anywhere in the world,[67] there are geographic areas with relatively high levels of resistance to macrolide antibiotics.[68,69] The average macrolide resistance in a US multicenter study in 2002 was 6.1% (range, 3%–8.7%).[70] A prospective, multicenter, US community–based surveillance study of pharyngeal GAS isolates recovered from children 3 to 18 years of age during three successive respiratory seasons between 2000 and 2003 found macrolide resistance of less than 5% and clindamycin resistance of 1% and found no evidence of increasing erythromycin minimum inhibitory concentrations over the 3-year study period.[71] There was, however, considerable geographic variation in macrolide resistance rates in each study year and year-to-year variation at individual study sites.

Higher resistance rates have been reported occasionally. For example, 9% of pharyngeal and 32% of invasive GAS strains collected in a San Francisco study during 1994 to 1995 were macrolide resistant.[72] During a longitudinal investigation of GAS disease in a single elementary school in Pittsburgh, investigators found that 48% of isolates of GAS collected between 2000 and 2001 were resistant to erythromycin; none was resistant to clindamycin.[73] Molecular typing indicated that this outbreak was caused by a single strain of GAS. Clinicians should be aware of local rates of resistance and the risk of changes in a short period.

Other Treatment Considerations

There is no evidence from controlled studies to guide therapy of acute pharyngitis when β-hemolytic group C or group G streptococci are isolated. If a physician elects to treat, the regimen should be similar to that for GAS pharyngitis, with penicillin as the antimicrobial agent of choice.[10]

Acyclovir treatment of HSV gingivostomatitis initiated within 72 hours of the onset of symptoms shortens the duration of illness.[74] Although use of antiviral medications for primary EBV pharyngitis can interrupt viral replication temporarily, symptomatic relief is negligible and does not justify the use of acyclovir.

Corticosteroids are recommended for EBV pharyngitis only when tonsillar enlargement threatens airway patency or for other systemic disease such as myocarditis or massive splenomegaly.[18] Several reviews (including a 2012 Cochrane review) of heterogeneous studies of the use of corticosteroids for GAS and non-GAS pharyngitis found a small but measurable benefit in pain reduction, especially when initiated early in the course of severe illness.[75–79] However, an increase in deep neck infections has been temporally associated with increased use of anti-inflammatory medications, including corticosteroids, for pharyngitis.[80] The modest and short-lived benefit of treatment must be weighed against the potential for harm. Use of corticosteroids for pharyngitis is not recommended by the AAP or IDSA.[17]

Treatment Failures, Chronic Carriage, and Recurrences

Antimicrobial treatment failure of GAS pharyngitis can be classified as clinical or bacteriologic failure. The significance of *clinical treatment failure* (i.e., persistent or recurrent signs or symptoms suggesting GAS pharyngitis) is difficult to determine without repeated isolation of the infecting strain of GAS (i.e., true bacteriologic treatment failure).

Bacteriologic treatment failures can be further classified as true or apparent. *True bacteriologic failure* refers to the inability to eradicate the specific strain of GAS causing an acute episode of pharyngitis with a complete course of appropriate antimicrobial therapy. In the absence of penicillin resistance, the following factors have been suggested but not established definitively as causes: penicillin tolerance (i.e., discordance between the concentration of penicillin required to inhibit and to kill the organisms)[81,82]; enhancement of colonization and growth of GAS by pharyngeal flora or inactivation of penicillin by production of β-lactamases[67]; and resistance of intracellular organisms to antimicrobial killing.[83]

Apparent bacteriologic failure can occur when newly acquired GAS isolates are mistaken for the original infecting strain, when the infecting strain of GAS is eradicated but then is rapidly reacquired, or when adherence to antimicrobial therapy is poor. However, most bacteriologic treatment failures are manifestations of the GAS carrier state. *Chronic carriers* have no clinical illness or immunologic response to the organism, can be colonized for 6 to 12 months or longer, are unlikely to spread GAS to close contacts, and are at very low or no risk for developing suppurative or nonsuppurative complications.[84,85]

During the winter and spring in temperate climates, as many as 20% of asymptomatic school-aged children carry GAS.[84] GAS carriers should not be sought or given antimicrobial therapy; the primary approach to the suspected or confirmed carrier is reassurance. A throat culture or RADT should be performed if the patient has symptoms and signs suggesting GAS pharyngitis but should be avoided when symptoms are more typical of viral illnesses (see Box 27.1). Each clinical episode confirmed with a positive culture or RADT should be treated. Identification and eradication of the streptococcal carrier state are desirable in rare specific situations. When antimicrobial therapy is employed, oral clindamycin (30 mg/kg/day up to 900 mg, divided into 3 doses) for 10 days is preferred, but intramuscular benzathine penicillin (alone or in combination with procaine penicillin) plus oral rifampin (20 mg/kg/day divided into 2 doses; maximum dose of 300 mg for 4 days beginning on the day of the penicillin injection[86]) also is effective. Chronic carriage can recur on re-exposure to GAS.

In a patient with symptoms suggesting GAS after treatment, a throat culture or RADT usually is performed. If the result is positive, many clinicians elect to administer a second course of penicillin therapy.

The patient with repeated episodes of acute pharyngitis associated with a positive throat culture or RADT result is a common and difficult problem for the practicing physician. The fundamental question is whether the patient is experiencing repeated episodes of GAS pharyngitis or is a GAS carrier experiencing repeated episodes of viral pharyngitis. The latter situation is by far the more common.

The patient is likely to be a GAS carrier if: (1) clinical and epidemiologic findings suggest a viral cause, (2) there is little clinical response to appropriate antimicrobial therapy, (3) the throat culture or RADT result is positive between episodes of pharyngitis, and (4) there is no serologic response to GAS extracellular antigen (e.g., ASO, anti-deoxyribonuclease B). In contrast, the patient with repeated episodes of acute pharyngitis associated with positive throat cultures or RADT results is likely to be experiencing repeated episodes of GAS pharyngitis if (1) clinical and epidemiologic findings suggest GAS pharyngitis, (2) there is a demonstrable clinical response to appropriate antimicrobial therapy, (3) the throat culture or RADT result is negative between episodes of pharyngitis, and (4) there is a serologic response to GAS extracellular antigens.

If it is determined that the patient is experiencing repeated episodes of true GAS pharyngitis, some physicians have suggested use of oral penicillin V prophylactically. However, the efficacy of this regimen has not been proved, and antimicrobial prophylaxis is not recommended except to prevent recurrences of rheumatic fever in patients who have experienced a previous episode of rheumatic fever. Tonsillectomy may be considered in the rare patient whose symptomatic episodes do not diminish in frequency over time and in whom no alternative explanation for the recurrent GAS pharyngitis is evident. However, tonsillectomy has been beneficial for a relatively small group of these patients, and any benefit is relatively short lived.[87,88] A 2014 Cochrane review found that children who had tonsillectomy had 3 episodes of sore throat in the first year after surgery compared with 3.6 episodes per year for those who did not have tonsillectomy and that children with more severe or more frequent episodes received the largest benefit.[89]

Complications

GAS pharyngitis can be associated with suppurative and nonsuppurative complications (see Chapter 118). Suppurative complications result from the spread of GAS to adjacent structures and include peritonsillar abscess, parapharyngeal and retropharyngeal abscess, cervical lymphadenitis, sinusitis, otitis media, and mastoiditis. Before antimicrobial agents were available, suppurative complications of GAS pharyngitis were common, but antimicrobial therapy has greatly reduced the frequency of these complications.

Infections of the Upper and Middle Airways

Marc Tebruegge, Nigel Curtis

Supraglottic infections comprise peritonsillar abscess, retropharyngeal abscess, parapharyngeal abscess, and epiglottitis. Infections of the middle airways include croup (i.e., laryngotracheitis) and bacterial tracheitis. All of these conditions share the potential for respiratory compromise and airway obstruction. Table 28.1 summarizes the typically affected age groups, common clinical features at presentation, and the most commonly implicated organisms. Differentiation from other airway infections is discussed in Chapter 21 (see Table 21.4).

TABLE 28.1

Clinical Features and Causative Organisms of Infections of the Upper and Middle Airways

Disease	Typical Age Group	Potential Initial Infection	Key Clinical Findings	Typical Organisms
Peritonsillar abscess	Adolescents	Pharyngotonsillitis	Sore throat, odynophagia, dysphagia, peritonsillar swelling, uvular deviation to	*Streptococcus pyogenes*

			contralateral side, muffled voice	
Retropharyngeal abscess	<5 yr	Pharyngitis, tonsillitis, adenitis	Sore throat, odynophagia, dysphagia, neck pain and swelling, limited neck mobility, torticollis	*Streptococcus pyogenes,* viridans streptococci, *Staphylococcus aureus, Haemophilus* and *Neisseria* spp., anaerobic bacteria; often polymicrobial
Parapharyngeal abscess	All age groups	Pharyngitis, tonsillitis, adenitis, otitis media	Sore throat, odynophagia, dysphagia, neck pain and swelling, torticollis, deviation of the lateral wall of the oropharynx to the midline	Same as for retropharyngeal abscess
Lemierre syndrome (primary oropharyngeal infection; septicemia; thrombophlebitis of the internal jugular vein; metastatic infection at distant sites)	Adolescents	Pharyngitis, tonsillitis, adenitis, otitis media, mastoiditis	High-grade fever, neck pain and swelling, dysphagia, nausea and vomiting, hypotension; pulmonary involvement: dyspnea, hemoptysis, pleuritic chest pain	*Fusobacterium necrophorum*
Epiglottitis	In Hib-unimmunized populations: children <4 yr; in Hib-immunized populations: school-age children	—	Unwell looking, high-grade fever, stridor, drooling, muffled voice, tripod position with neck extension	*Haemophilus influenzae* type b
Croup (laryngotracheitis)	6 mo to 2 yr	—	Inspiratory stridor, barking cough, hoarseness; symptoms typically worsen during nighttime	Parainfluenza virus, influenza virus, respiratory syncytial virus
Bacterial tracheitis	2 to 10 yr	—	Moderate- to high-grade fever, cough, stridor, dyspnea, retractions; rapid	*Staphylococcus aureus*

			deterioration is common	

Peritonsillar Abscess

Peritonsillar abscess (i.e., quinsy) is the most common deep oropharyngeal infection.[1] Although rare, it usually is a complication of pharyngotonsillitis. The infection primarily affects adolescents and young adults, but it can occur at any age.

Etiologic Agents.

Streptococcus pyogenes is the most commonly isolated aerobic bacterium in cases with peritonsillar abscess.[2–9] Other streptococci, *Staphylococcus aureus*, and *Haemophilus influenzae* are less frequently implicated. Anaerobic bacteria, including *Prevotella*, *Bacteroides*, and *Peptostreptococcus* species, also are common isolates.[10] Polymicrobial infection occurs in some cases.[10]

Epidemiology and Pathogenesis.

The peak incidence of peritonsillar abscess is in adolescence and early adult life.[1,3,7,11–14] However, although uncommon, peritonsillar abscess can occur in very young children, including infants.[15–17] There is no clear sex predilection.

Peritonsillar abscess traditionally has been thought to result from extension of acute exudative pharyngotonsillitis. However, there is some evidence to suggest that this condition also can result from abscess formation within Weber salivary glands located in the supratonsillar fossa.[18]

Clinical Manifestations and Diagnosis.

At presentation, the patient usually has a severe sore throat and odynophagia.[7,11,13] Difficulty with swallowing often leads to decreased oral intake, which can result in dehydration.[13] Symptoms may worsen, and the patient may become unable to swallow saliva, causing drooling. Fever is reported in most cases, but it is not universal.[13] Common clinical signs at initial presentation include peritonsillar swelling, muffling of the voice, cervical lymphadenopathy, trismus, and uvular deviation toward the contralateral tonsil.[11,13] Bilateral disease is very rare.[12,19]

Inflammatory markers, including the white blood cell (WBC) count and C-reactive protein (CRP) level, are frequently elevated.[11,13] When there is doubt about the diagnosis, transcutaneous or intraoral ultrasound or computed tomography (CT) can be useful for confirmation.[20–23]

Management.

Peritonsillar abscess requires drainage, which can be achieved by needle aspiration, incision and drainage, or tonsillectomy (for quinsy).[13,14] Pus obtained during the procedure should be sent for Gram stain and routine and anaerobic culture. Intervention practices vary widely,[24] and there are no convincing data to suggest that one approach is superior to another.[25–28] Data from a nationwide study of more than 20,000 children with peritonsillar abscess admitted to US hospitals show that approximately half were managed conservatively, whereas incision and drainage was performed in more than one third of cases; fewer than 20% underwent tonsillectomy.[29]

Antibiotic therapy is empiric and should provide sufficient coverage for anaerobic and β-lactamase–producing bacteria. Suggested regimens include penicillin combined with metronidazole, amoxicillin-clavulanate, ampicillin-sulbactam, cefoxitin, and clindamycin.[7,30–34]

The role of adjuvant corticosteroid treatment remains controversial.[11,25,35,36] Data from one randomized, controlled trial (RCT) suggest that corticosteroids may expedite symptomatic improvement in adults.[37] The choice about whether to treat a patient with peritonsillar abscess on an outpatient or inpatient basis should take into account the patient's age, coexisting morbidities, and the need for intravenous hydration, pain control, and airway monitoring.[13]

Complications and Prognosis.

A small proportion of patients require intensive care support, usually for management of airway compromise.[11] The course of the illness can be complicated by contiguous extension of infection to the retropharyngeal or parapharyngeal space.[11,12] Other potential complications include aspiration pneumonia and mediastinitis.

The prognosis for appropriately managed peritonsillar abscess is good. A fatal outcome is rare. Relapse or recurrence occurs in approximately 5% to 10% of cases.[11–13,19]

Retropharyngeal Abscess

The retropharyngeal space extends from the base of the skull to the upper thoracic spine. The anterior border of this space is formed by the constrictor muscles of the pharynx, the lateral borders by the carotid sheaths, and the posterior border by the prevertebral fascia.

Etiologic Agents.

Polymicrobial infection is common; mixed aerobic and anaerobic infection occurs frequently.[38–43] Commonly implicated aerobic bacteria include *S. pyogenes*, viridans streptococci, *S. aureus,* and *Haemophilus* and *Neisseria* species.[a] Methicillin-resistant *S. aureus* (MRSA) as a cause varies geographically.[41,42] A series from Texas highlighted MRSA as a more frequent cause than methicillin-susceptible *S. aureus* (MSSA).[49] Common anaerobic isolates include *Peptostreptococcus*, *Prevotella*, *Bacteroides,* and *Fusobacterium* species.

Epidemiology and Pathogenesis.

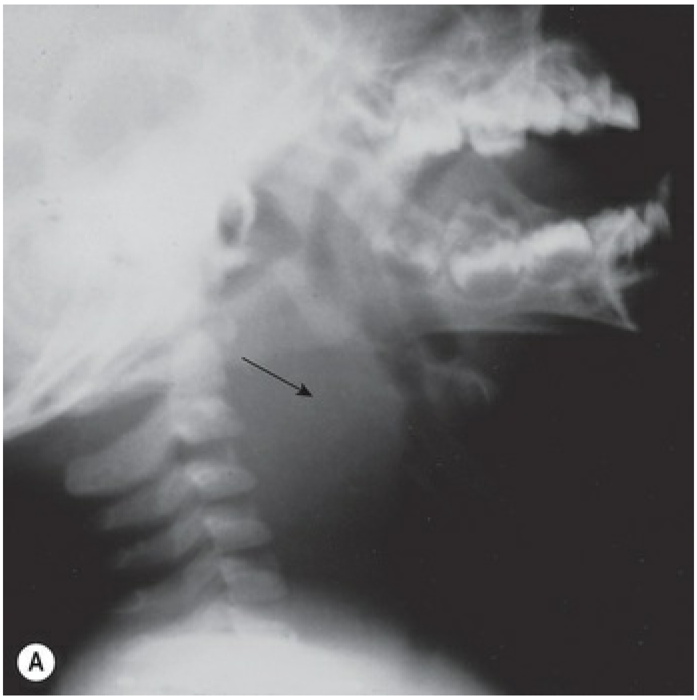
Retropharyngeal abscess can occur at any age, but most commonly affects children younger than 5 years of age.[7,38,45,49–52] In most reports, there is some male predominance.[b] The US incidence peaks during the winter and spring months, and the same has been reported in Europe.[45,46,48,53] Some data suggest that the US incidence of retropharyngeal abscess has increased over the past decade.[38,41,43,49] Similar observations have been reported from the UK.[55]

Retropharyngeal abscess in children predominately results from infection and suppuration of the retropharyngeal chains of lymph nodes, which drain the nasopharynx, the paranasal sinuses, and the adenoids.[38,40–43,46] Common primary infections include pharyngitis, tonsillitis, adenitis, and less frequently, sinusitis, otitis media, mastoiditis, and dental infections. Unlike in adults, local trauma and foreign body ingestion play a relatively minor role in children.[c]

Clinical Manifestations and Differential Diagnosis.

Common presenting features include pyrexia, sore throat, dysphagia, odynophagia, neck pain, neck swelling, limited neck mobility (particularly on extension), and torticollis.[d] Trismus is uncommon, but drooling can occur. Most patients have evidence of pharyngitis or tonsillitis and cervical lymphadenitis on examination.[44,52] In most reports, the proportion of patients with symptoms that indicate airway obstruction, such as difficulty in breathing and stridor, is relatively small.[41,43–46,50,52] Airway obstruction in the context of retropharyngeal abscess predominately occurs in infants and very young children.[41–43]

Peripheral blood leukocytosis is common.[e] The CRP level and erythrocyte sedimentation rate (ESR) usually are elevated.[49,52] In most cases, enlargement of the retropharyngeal space/prevertebral tissue can be seen on plain lateral neck radiographs (Fig. 28.1).[38,43,44,56] However, CT is more sensitive and is the imaging modality of choice.[43,45,50,56–62]



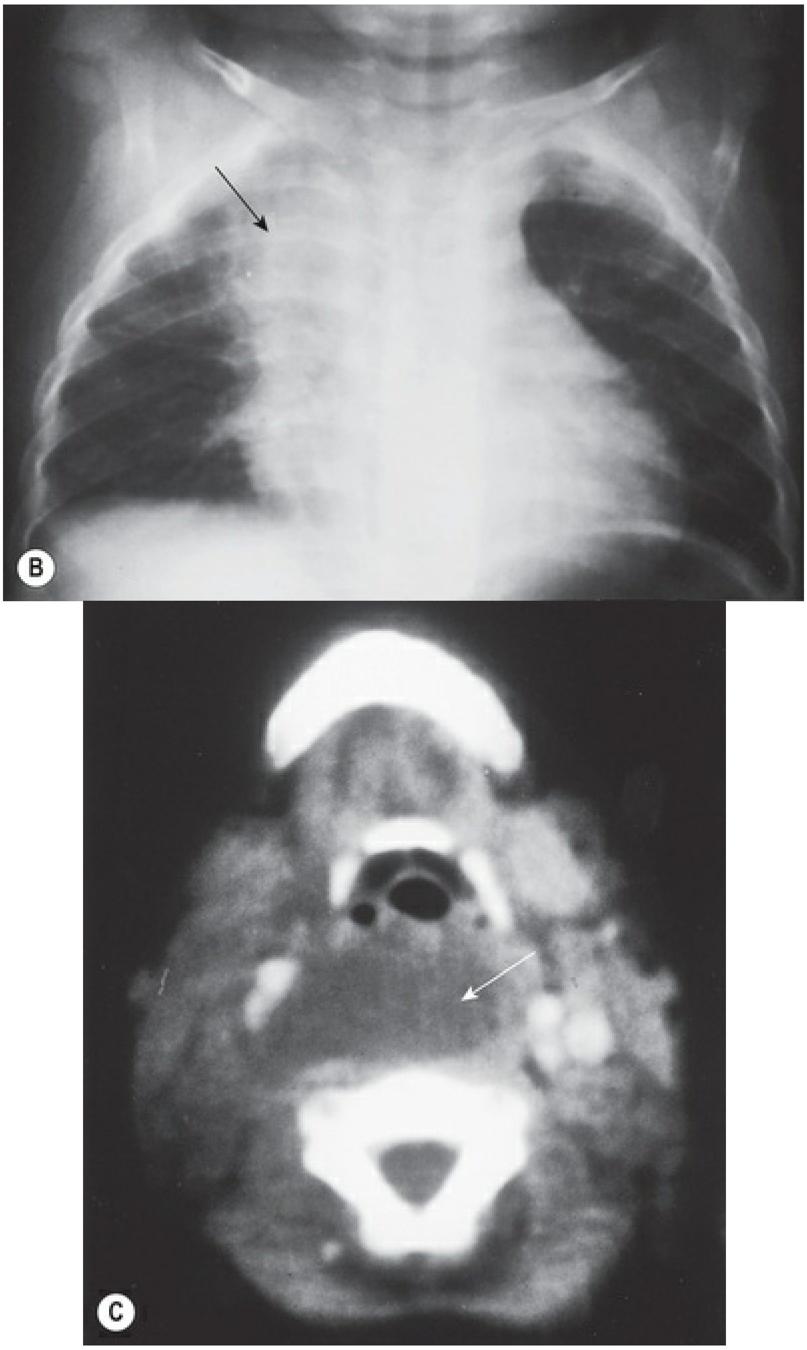


FIGURE 28.1 (A) Lateral neck radiograph of an 18-month-old toddler shows a retropharyngeal abscess due to *Staphylococcus aureus* infection. Notice the marked retropharyngeal soft tissue density *(arrow)* with anterior displacement of the hypopharynx and the laryngotracheal airway and the normal appearance of the epiglottis, glottis, and subglottic airway. (B) The chest radiograph shows an extension of the infection into the mediastinum *(arrow)*. (C) Computed tomography scan without contrast of the upper cervical region shows an abscess in the retropharyngeal space *(arrow)* with anterior displacement and compression of the airway and lateral displacement of the great

vessels. Bony structures are the mandible *(top)*, hyoid bone, and the cervical vertebrae. (Courtesy of Richard H. Schwartz, MD, Vienna, VA.)

Management.

There is no consensus about the optimal empiric antibiotic treatment. Penicillin or ampicillin alone is insufficient because β-lactamase–producing organisms, *S. aureus,* and mixed infections are common. Appropriate empiric antibiotic regimens include a second- or third-generation cephalosporin plus clindamycin or metronidazole, amoxicillin-clavulanate, ampicillin-sulbactam, and piperacillin-tazobactam.[f] Some physicians think that clindamycin alone may be sufficient.[40,54] Local patterns of susceptibility of *S. aureus* and the clinical state of the patient should be taken into account, frequently leading to a combination of antibiotics that includes clindamycin or vancomycin.[49]

The role of surgical drainage remains controversial.[g] Patients with significant respiratory distress require urgent airway management and surgical drainage. However, there is debate about whether a trial of conservative management with intravenous antibiotics for a 24- to 48-hour period in conjunction with close monitoring is appropriate for patients who are stable and have no respiratory distress.[38,44–46,50] The reported success rates with conservative management alone vary considerably between studies, and there have been no randomized trials.[h] Surgical drainage usually is performed using the transoral approach and less commonly using the transcervical route.[i]

Complications and Prognosis.

Potential complications include airway obstruction, internal jugular vein thrombosis, mycotic aneurysm of the carotid artery, aspiration pneumonia, mediastinitis, and sepsis, although these are rare overall.[j] Few patients require repeated surgical intervention.[43,45,49] Most patients have an uncomplicated course and can be discharged on oral antibiotics within a few days.[41,42] Fatal outcomes have been rare in recent studies.

Parapharyngeal Abscess

The lateral pharyngeal space (i.e., parapharyngeal space) is shaped like an inverted cone extending from the base of the skull to the hyoid bone. It is bound medially by the superior pharyngeal constrictor muscle and laterally by the internal pterygoid muscle.[69] The lateral pharyngeal space contains the internal carotid artery, the internal jugular vein, cranial nerves IX to XII, the sympathetic chain, and the lymph nodes. This space is separated from the retropharyngeal space by only the alar fascia, which provides little barrier against the spread of infection.[69] Simultaneous infection of both compartments is common, and some investigators think that a distinction between parapharyngeal and retropharyngeal abscess is not meaningful clinically.[46,65,69–71]

Etiologic Agents, Epidemiology, and Pathogenesis.

The spectrum and frequency of causative organisms are similar to those reported for retropharyngeal abscess.[30,72] Studies of deep neck space infections in children suggest that parapharyngeal abscesses are less common than retropharyngeal abscesses.[7,31,45,52] Unlike retropharyngeal abscess, parapharyngeal abscess occurs in all age groups without a predilection for younger children.[51,73] Parapharyngeal abscess is thought to result primarily from infection and subsequent suppuration of lymph nodes in the lateral pharyngeal space, which are part of the lymphatic drainage of the nasopharynx and middle ear.[73–76] In many cases, there is a history of preceding pharyngitis or tonsillitis.

Clinical Manifestations and Differential Diagnosis.

The clinical features of parapharyngeal abscess closely resemble those associated with retropharyngeal abscess.[69] Fever and neck swelling are common; patients also can have dysphagia, odynophagia, torticollis, or trismus.[k] A common feature distinguishing parapharyngeal abscess from retropharyngeal abscess is deviation of the lateral wall of the oropharynx to the midline on oral inspection.[73,77–79]

Peripheral blood leukocytosis and an elevated CRP level are common.[66,74] Contrast-enhanced CT is the imaging modality of choice for investigating suspected cases.[l] Plain lateral neck radiographs are not useful.[45]

Management, Complications, and Prognosis.

Management of parapharyngeal abscess is similar to that for retropharyngeal abscess. There is ongoing controversy among experts about whether surgery is mandatory in all patients.[m] Traditionally, an external cervical approach has been used for the drainage of parapharyngeal abscesses,[7,60,81] but transoral drainage has been reported to be safe and effective in selected cases with abscess location medial to the great vessels.[69,71,76,77,81] The transoral approach has cosmetic advantages, and the intraoperative time usually is shorter.[81]

Potential complications comprise internal jugular vein thrombosis, erosion of the carotid artery, airway obstruction, aspiration pneumonia, pleural empyema, mediastinitis, pericarditis, and septic shock.[n] Fatal outcomes and long-term sequelae are rare.[31,70,73]

Lemierre Syndrome

The first description of Lemierre syndrome was published in 1900 by Courmont and Cade,[84] followed by a report by Schottmüller in 1918.[85] The clinical syndrome, also referred to as *necrobacillosis*, is named in honor of André Lemierre, who described a series of 20 cases of “postanginal septicemia” in 1920.[86] Lemierre syndrome is characterized by primary infection of the oropharynx, blood culture–confirmed septicemia, evidence of thrombophlebitis of the internal jugular vein, and metastatic infection at one or more distant sites.[87]

Etiologic Agents.

Fusobacterium necrophorum is by far the most commonly implicated etiologic agent in cases of Lemierre syndrome.[87–90] *F. necrophorum* is an obligate anaerobic, gram-negative bacillus that is part of the normal flora of the oral cavity and the gastrointestinal and female genital tract. Most strains are susceptible to second- and third-generation cephalosporins, clindamycin, and metronidazole; a significant proportion of clinical isolates produce β-lactamase.[91–93]

Other causative bacteria associated with Lemierre syndrome include other *Fusobacterium* species, *Bacteroides* species, *Prevotella* species, streptococci (mainly non–group A), and infrequently staphylococci.[87,88,90,94–96] Mixed infections also occur.[89,95]

Epidemiology and Pathogenesis.

Despite the absence of solid epidemiologic data, most experts agree that the incidence of the disease declined considerably during the antibiotic era. Lemierre syndrome currently is uncommon, with an estimated annual incidence of approximately 1 case per 1 million people.[97] However, some data suggest that the incidence has increased in recent years.[98] The disease typically affects teenagers and young adults,[o] although a few cases in infancy have been described.[91,100] There appears to be male predominance.[87,101] Most cases have no predisposing illness.

In most cases, the disease process begins with a primary focus of infection in the oropharynx (e.g., palatine tonsils, peritonsillar tissue). Other infections in the head and neck area, including sinusitis, otitis, mastoiditis, parotitis, and odontogenic infections, are less common sources.[p] The infection subsequently spreads to the lateral pharyngeal space or parapharyngeal space. Further progression results in infectious thrombophlebitis of the internal jugular vein, which causes septic pulmonary emboli and metastatic infection at other distant sites. The lungs are the most commonly involved secondary site, followed by joint and soft tissue infections,[87,88,95,101] Other manifestations, such as skin infection, osteomyelitis, liver abscess, splenic abscess, and meningitis, are rare.[87,91,101,104–107]

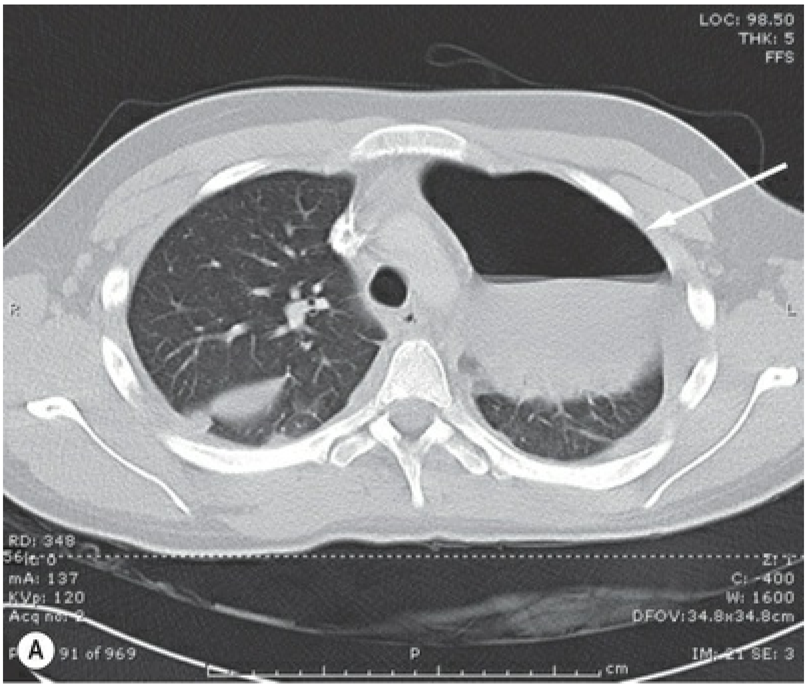
Clinical Manifestations and Differential Diagnosis.

The presenting features of Lemierre syndrome depend partly on the primary site of infection. Most cases are diagnosed within 7 days of onset of the primary infection.[87] In patients with an oropharyngeal source, inspection may reveal exudative tonsillitis, hyperemia, or grayish pseudomembranes. An unremarkable oropharyngeal appearance at the time of septicemia does not rule out Lemierre syndrome.[87,108] Patients with otitis media or mastoiditis as the primary focus can have otorrhea or postauricular fluctuation.[91,109] Most patients have high-grade pyrexia (>39.5°C) at presentation, although fever can be absent. Neck swelling and tenderness is seen in most cases.

Other symptoms and signs include trismus, dysphagia, dyspnea, hemoptysis, pleuritic chest pain, nausea and vomiting, jaundice, hepatomegaly, and hypotension. Severe shock and renal failure are uncommon despite the septicemic state.[87,94] Auscultation and percussion of the chest may reveal crepitations and evidence of pleural effusions in cases with pulmonary involvement.

The WBC count, CRP, and ESR often are markedly elevated.[q] Thrombocytopenia occurs in approximately a quarter of patients.[110] Levels of liver enzymes and bilirubin are sometimes not elevated.[87,95] Blood cultures typically are positive, but they may be sterile in patients who have taken antibiotics before samples were collected for culture.

Contrast-enhanced CT of the neck is the most useful investigation. Possible CT findings include distended neck veins, intraluminal filling defects, and soft tissue swelling.[95,100,111,113,114] Doppler ultrasonography and magnetic resonance imaging are also useful in this setting. The chest radiograph and chest CT may reveal pulmonary infiltrates, pulmonary cavitation, or pleural effusions (Fig. 28.2).



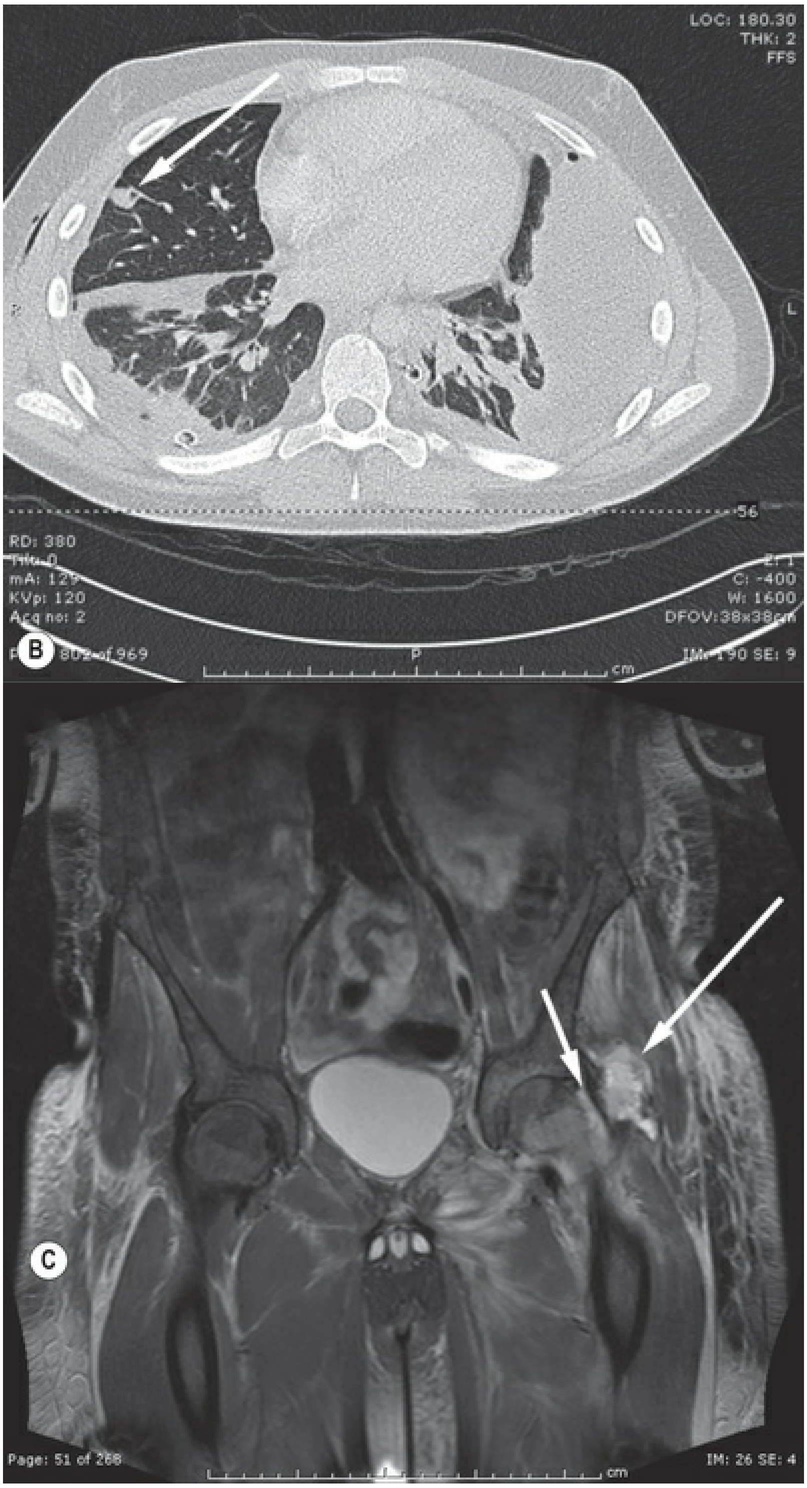


FIGURE 28.2 (A) Chest computed tomography scan of a 16-year-old patient with Lemierre syndrome with marked pulmonary involvement shows a large, left-sided pneumothorax *(arrow)* and adjacent empyema. (B) Chest computed tomography scan of the same patient shows widespread bilateral pulmonary consolidation and nodular foci. The central cavitation in the lesion is marked by an *arrow*. (C) Coronal magnetic resonance image shows the hip region in the same patient, who also developed septic arthritis of the

left hip joint and abscess formation in the adjacent muscles. Notice the synovial enhancement *(small arrow)* and the fluid collection *(large arrow)*, which extended anteriorly between the iliopsoas, the rectus femoris medially, and the gluteus muscles laterally.

Management.

Antibiotic treatment is the mainstay of therapy. Common empiric regimens include high-dose penicillin with metronidazole, clindamycin, ticarcillin-clavulanate, and ampicillin-sulbactam.[r] Due to the endovascular nature of the infection, intravenous therapy is required for several weeks.

Surgical debridement of necrotic tissues and drainage of abscess or empyema often are required in conjunction with medical therapy. Ligation or resection of the internal jugular vein was a common therapeutic intervention in the preantibiotic era. However, this is rarely necessary and should be restricted to unstable patients who fail to respond to conservative therapy.[98,110,111,116] The role of routine anticoagulation therapy in Lemierre syndrome continues to be controversial.[s]

Complications and Prognosis.

Metastatic infections can cause complications depending on their location. Pleural effusions, empyema, lung abscesses, and pulmonary cavitation can occur in patients with Lemierre syndrome. Pneumatocele and pneumothorax can occur. Septic pyogenic arthritis typically affects larger joints, such as the shoulder, elbow, and hip joints (see Fig. 28.2).[87,101] Renal involvement can be associated with proteinuria or hematuria.

In the preantibiotic era, the prognosis was poor, with fatality rates as high as 90% in some historical reports.[86,102] Recent reviews of the literature suggest that fatal outcomes are uncommon, typically between 5% and 10%.[87,88]

Acute Epiglottitis

The incidence of invasive *Haemophilus influenzae* type b (Hib) disease decreased dramatically, and epiglottitis (i.e., supraglottitis) has become a rare disease in countries where Hib vaccines are used routinely.[118–129] Data from England and Wales show that the incidence of invasive Hib disease after 2 decades of routine immunization fell to 0.02 cases per 100,000 inhabitants.[130] Necrotizing epiglottitis is a rare variant, which has been reported predominately among immunocompromised patients.[131]

Etiologic Agents.

Hib infection accounted for approximately 75% to 90% of epiglottitis cases in the pre-Hib vaccination era.[119,126,132] Currently, only rare cases due to vaccination failure are reported.[t] Other organisms implicated in epiglottitis are *S. pyogenes*, *S. pneumoniae*, *S. aureus*, nontypeable *H. influenzae*, *H. parainfluenzae*, *Pseudomonas* species, *Klebsiella* species, and *Moraxella catarrhalis*.[119,126,132,137–140]

Epidemiology and Pathogenesis.

In the pre-Hib vaccination era, the incidence of epiglottitis peaked in early childhood, typically affecting children younger than 4 years of age.[132,137,141] After institution of universal Hib vaccination, the peak incidence shifted toward an older age group, with a simultaneous increase in the proportion of adult cases.[u] Many studies show no sex predominance, while others report some male predominance.[122,132,143–145] There is little seasonal variation in incidence in temperate climates.[129,143–146]

Acute epiglottitis is a localized, invasive bacterial infection of the supraglottic area, comprising the epiglottis, arytenoid cartilages, aryepiglottic folds, and false vocal chords. Inflammation results in airway edema and narrowing, which leads to airway obstruction manifesting as stridor and respiratory distress. The localized infection can evolve into phlegmon and abscess formation. Bacteremia is common in cases caused by Hib, but dissemination to distant sites (e.g., causing septic arthritis or meningitis) is rare.

Clinical Manifestations and Diagnosis.

Children with epiglottitis typically look systemically unwell and have high-grade fever and stridor.[122,137,145] Aphonia, hoarseness, and a muffled, “hot potato” voice are common features.[129,137] Odynophagia is common, and drooling frequently is observed. Most patients assume an upright tripod position with forward leaning and extension of the neck.[147] Cervical lymphadenopathy also is a common feature.[137]

Peripheral blood leukocytosis is present in most cases.[129,137,140,146] Lateral neck radiographs demonstrate epiglottic enlargement with a distended hypopharynx, a classic thumb sign that has high sensitivity (Fig. 28.3). However, this should be attempted only for a stable, cooperative patient in a safe environment because performing radiography in the lateral position can precipitate respiratory arrest from complete airway obstruction, especially if the child's neck is repositioned for optimal results.[133,137]

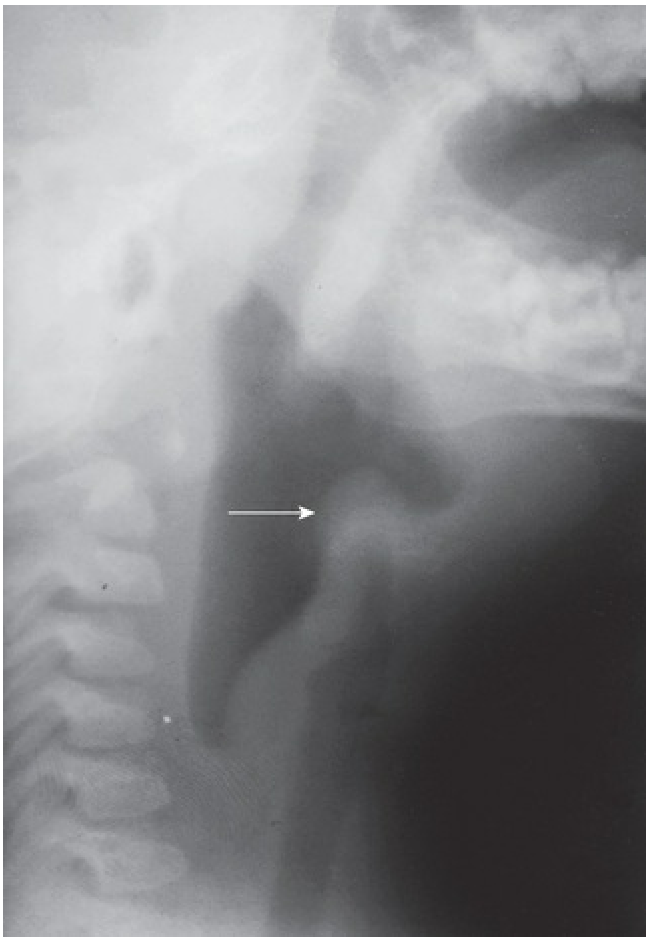

FIGURE 28.3 Lateral neck radiograph of a 4-year-old child with acute epiglottitis shows the characteristically distended hypopharynx and “thumbprint” edematous epiglottis and aryepiglottic folds *(arrow)*. (Courtesy of Richard H. Schwartz, MD, Vienna, VA.)

Management.

Effective airway management is critical. Upsetting the child during attempts to inspect the oropharynx can result in complete airway obstruction. Nebulized epinephrine (i.e., adrenaline) can provide some transient improvement in respiratory distress but also can cause agitation and precipitate airway obstruction. Unstable patients should be urgently intubated by direct laryngoscopy or bronchoscopy in a controlled setting (i.e., operating room or intensive care unit). Although rarely required, facilities to perform a tracheostomy must be available in case attempts to intubate fail.[122,129,137,143] There continues to be controversy about whether cases at the mild end of the disease spectrum without significant respiratory distress can be managed safely without intubation while being closely monitored.[129,137,148]

Blood cultures and throat or epiglottic swabs (in intubated cases) should be obtained for culture and susceptibility testing. Empiric antibiotic therapy, such as a third-generation cephalosporin or ampicillin-sulbactam, should be commenced promptly.[v] The routine use of corticosteroids, which is intended to reduce airway edema, remains controversial, and no RCT has addressed this question.[120,140,148] However, previous, uncontrolled studies have not shown a clear benefit regarding the need for intubation, duration of ventilation, or duration of hospital stay.[137,140,146]

In cases with confirmed Hib epiglottitis, prophylaxis with rifampin should be considered for household contacts according to American Academy of Pediatrics recommendations.[150] The latest UK guidelines also recommend the use of rifampin and suggest ciprofloxacin or azithromycin as an alternative for people who cannot tolerate rifampin or in whom rifampin can interfere with other drugs.[151]

Complications and Prognosis.

Potential complications include complete airway obstruction and cardiac arrest, epiglottic abscess, deep neck infection, pneumonia, and seizures.[122,129,132,137] Most patients require only a short period of intubation and ventilation and can be extubated in 24 to 72 hours.[122,129,132,145] The mortality rate is less than 5% in settings where good intensive care support is available.[129,132,137,141,143]

Croup

Viral croup (i.e., laryngotracheitis) is the most common cause of infectious upper airway obstruction in young children. Some physicians prefer to divide croup into spasmodic croup and laryngotracheitis, also referred to as laryngotracheobronchitis.[152] However, in the clinical setting, this distinction is not particularly meaningful, and *croup* is therefore used in this chapter.

Etiologic Agents and Epidemiology.

Parainfluenza virus types 1, 2, and 3 are the most common causative agents of croup, accounting for 50% to 80% of cases, followed by influenza A, influenza B, and respiratory syncytial virus.[153–159] Less common etiologic agents include adenoviruses, rhinoviruses, coxsackieviruses, and echoviruses.[153,154,158,160] Studies have associated human metapneumovirus, human bocavirus, and human coronavirus NL63 with croup.[160–167] Some data suggest that the clinical course of croup caused by influenza virus is more severe than croup caused by parainfluenza virus.[153]

Epidemiology and Pathogenesis.

Croup is common. One study from Seattle estimated the annual incidence to be as high as 7 cases per 1000 children younger than 6 years of age.[158] The incidence of croup is highest among children between the ages of 6 months and 2 years.[154,156–158] Typical croup symptoms are rarely observed in children older than 6 years of age, likely because of the increase in airway diameter.[157] The incidence is higher among boys.[152–154,156,168] In temperate climates, the incidence typically peaks in late autumn and winter.[154,156,158,168,169]

Inflammatory edema and mucus production result in airway narrowing in the subglottic region, resulting in stridor.[147,152,170,171] Inflammation of the vocal chords results in hoarseness and sometimes in aphonia.

Clinical Manifestations and Differential Diagnosis.

The typical features of croup are inspiratory stridor, a barking cough, and hoarseness. Symptoms often start abruptly and typically worsen during the night.[172] Nonspecific coryzal symptoms frequently precede the illness. Most patients have low-grade or moderate-grade fever.[155,156] Less than 3% of cases in a primary care setting require hospitalization.[155,156]

Infectious and noninfectious causes and clinical features of upper airway obstruction, including croup, are delineated in Chapter 21 (see Tables 21.3–21.5). The noninfectious differential diagnosis includes foreign body aspiration, vocal chord dysfunction, laryngeal webs, allergic or hypocalcemic laryngospasm, subglottic stenosis (e.g., after prolonged intubation), tracheomalacia, H-type tracheoesophageal fistula, gastroesophageal reflux, and vascular ring.[153,172–175] Laryngeal diphtheria, now a rare but potentially life-threatening infection, can begin as severe croup.[172,176, 177]

The diagnosis of croup is made primarily on clinical grounds. Airway or chest radiographs are not indicated in cases with uncomplicated croup.[172,178,179] However, a radiograph showing narrowing of the subglottic airway can be useful if an alternative diagnosis is suspected. Respiratory viral panel testing by PCR can confirm a typical agent but frequently does not aid management.[172]

Management.

Treatment with mist or humidified air has been a key component of croup management for much of the 20th century,[152] although only a few published RCTs have investigated the effectiveness of humidified air in hospitalized patients.[180–183] There are no published data on the effectiveness of warm, humidified air in the home environment—a measure frequently recommended to parents.[184] A Cochrane review that included pooled data from three RCTs found that there was a modest, statistically not significant improvement in the croup severity score of patients receiving humidified air compared with untreated patients during the first hour of treatment; there was no difference between treatment groups for other outcome measures.[184]

Treatment with corticosteroids is routinely indicated.[152] A Cochrane review that included 31 RCTs showed that corticosteroid treatment was associated with significant improvement in the croup severity score at 6 and 12 hours compared with placebo.[185] Corticosteroid treatment was associated with a shorter duration of stay in the emergency department or hospital, fewer admissions, and fewer return visits. However, a range of different corticosteroids (e.g., dexamethasone, budesonide, methylprednisolone, fluticasone), different routes of administration (e.g., oral, intramuscular, inhalation), and doses were used in the trials. Most experts recommend the use of oral or intramuscular dexamethasone (0.6 mg/kg) or nebulized budesonide (2 mg).[152,178,186–188] It remains unclear whether repeated doses over the first 48 hours improve outcome.[189]

Many studies have shown that nebulized epinephrine is effective for achieving symptomatic improvement in children with moderate to severe croup.[190–195] Some data suggest that the use of nebulized epinephrine results in a considerable reduction in the need for intubation or tracheostomy.[196] The drug can be administered as racemic epinephrine (2.25%; 0.5 mL in 2.5 mL of saline) or L-epinephrine (1:1000 solution; 5 mL). A 2013 Cochrane review concluded that the two drugs were equally effective.[197] The treatment is safe, and side effects such as pallor and tachycardia usually are mild and transient.[198]

For children with moderate croup (i.e., stridor and chest wall indrawing at rest) who fail to improve sufficiently within 4 to 6 hours of administration of a corticosteroid, hospitalization should be considered. Children with severe croup should receive a dose of a corticosteroid and be treated with nebulized epinephrine; repeated administration of nebulized epinephrine may be necessary. Intensive care support should be considered if there is an insufficient response. The effect of nebulized epinephrine lasts for only 1 to 2 hours.[190] After that, clinical symptoms can return to baseline or become more severe (i.e., rebound effect).[186]

Children with oxygen saturation below 92% on room air should be given supplemental oxygen. Several reports have described the use of heliox in treating croup with some promising results.[199–201] However, two Cochrane reviews concluded that there was insufficient evidence to support its use in this setting.[202,203]

The use of antitussive and decongestant agents is not recommended.[152,186] Treatment with antibiotics is not indicated unless clinical features or laboratory test results indicate a secondary bacterial infection.[152,173,186] In cases of severe croup caused by influenza A or B virus, treatment with neuraminidase inhibitors should be considered, although there are insufficient efficacy data for this approach in this setting.[152,202–206]

Complications and Prognosis.

Few patients with croup require intubation and ventilation.[153,154] Contiguous spread of the viral infection can occur and can cause otitis media, bronchiolitis, or pneumonia. Bacterial superinfection can lead to bacterial tracheitis (discussed later) or bronchopneumonia.

The prognosis for uncomplicated croup is very good. Symptoms largely resolve within 48 to 72 hours in most patients.[172] A fatal outcome is very rare.

Acute Laryngitis

Isolated, acute laryngitis is primarily a disease described in adolescents and adults.

Etiologic Agents.

Acute laryngitis is caused most commonly by viruses; the spectrum of causative agents is similar to that for croup.[207–211] Bacteria implicated in acute laryngitis include *S. pneumoniae*, *H. influenzae*, and *M. catarrhalis*.[212–214]

Clinical Manifestations and Management

The key features of acute laryngitis are a change in the normal pitch of the voice and hoarseness, which typically last for 3 to 7 days. Coexistence of nonspecific upper respiratory tract infection symptoms, such as coryza, sore throat, and cough, is common.

Acute laryngitis in previously healthy people usually is a self-limited viral disease. Treatment with antibiotics is not routinely indicated. A Cochrane review on this topic, which included two RCTs evaluating penicillin V and erythromycin versus placebo, concluded that routine antibiotic treatment has no proven benefit.[215]

Bacterial Tracheitis

The term *bacterial tracheitis* was first used in a publication by Jones and colleagues in 1979.[216] Earlier reports describe cases of *laryngotracheobronchitis* that closely resemble descriptions of bacterial tracheitis, suggesting that this entity was recognized previously.[217,218]

Etiologic Agents.

S. aureus is by far the most common causative organism.[125,219–221] Other bacteria commonly implicated in bacterial tracheitis are *S. pyogenes*, *S. pneumoniae*, *H. influenzae,* and *M. catarrhalis*. Cases attributed to a variety of other bacteria, including *Pseudomonas aeruginosa*, *Bacillus cereus*, *Escherichia coli*, *Prevotella* species, and *Bacteroides* species also have been reported, although they appear to be uncommon.[219–226]

Epidemiology and Pathogenesis.

Bacterial tracheitis is rare, with an estimated annual incidence below 0.1 case per 100,000 children in the United Kingdom and Australia.[220] Incidence data have not been published for other countries. Some data suggest that the incidence peaks during autumn and winter.[220] Bacterial tracheitis predominately affects young children, although a few adult cases have been described.[227–229]

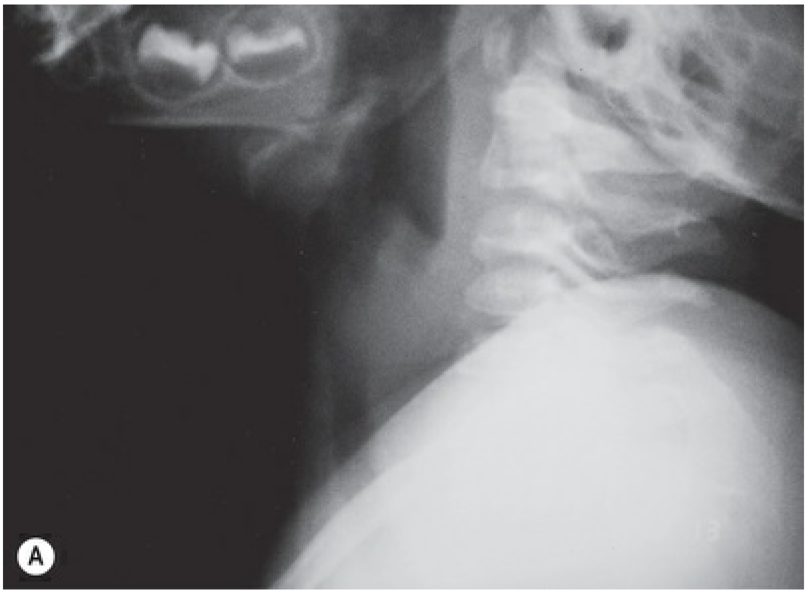
The pathogenesis of bacterial tracheitis remains unclear. It has been postulated that viral infection of the upper respiratory tract may facilitate secondary bacterial infection and invasion of the airways, resulting in inflammation and edema, which ultimately leads to narrowing of the trachea.[219] The peak incidence of bacterial tracheitis coincides with the peak season for viral respiratory pathogens, suggesting synergy. In one large case series, coinfection with influenza virus was identified in almost one third of the cases.[221] Coinfection with parainfluenza virus, respiratory syncytial virus, or adenovirus has been described in other reports.[125,220,223,230]

Clinical Manifestations and Differential Diagnosis.

Most patients with bacterial tracheitis report prodromal symptoms suggestive of a minor upper respiratory tract infection, which typically began 2 to 5 days before the onset of stridor.[219,220] After stridor and dyspnea develop, patients often deteriorate rapidly, frequently requiring intubation within the first 24 hours to overcome increasing upper airway obstruction.[216,220,231–233] Other common features at presentation include fever (often moderate to high grade), hoarse voice or aphonia, cough, and intercostal and subcostal recessions. Drooling is uncommon. Most cases show little or no response to nebulized epinephrine.[234]

The main differential diagnoses are epiglottis and viral croup. Unlike cases of bacterial tracheitis, children with epiglottitis typically refuse to speak, have drooling, and adopt an upright position with extension of the neck. Children with croup typically have only low-grade pyrexia, do not appear toxic, and usually respond to nebulized epinephrine.

An inflammatory response, including an elevated CRP level and WBC count, is seen in most patients at presentation.[220,234] The radiograph may demonstrate narrowing of the tracheal air shadow and intraluminal tracheal membranes, although these are not universal findings (Fig. 28.4).[223,230] Coexisting pulmonary changes, including infiltrates and atelectases, are common.[220,234–237] Direct visualization of the airways reveals an unremarkable or only mildly inflamed epiglottis but shows marked subglottic inflammation, edema of the tracheal mucosa, and copious purulent endotracheal secretions.[216,234] Endotracheal aspirates should be obtained and sent for bacterial culture and susceptibility testing. Blood cultures are rarely helpful, as bacteremia is relatively uncommon in these patients.



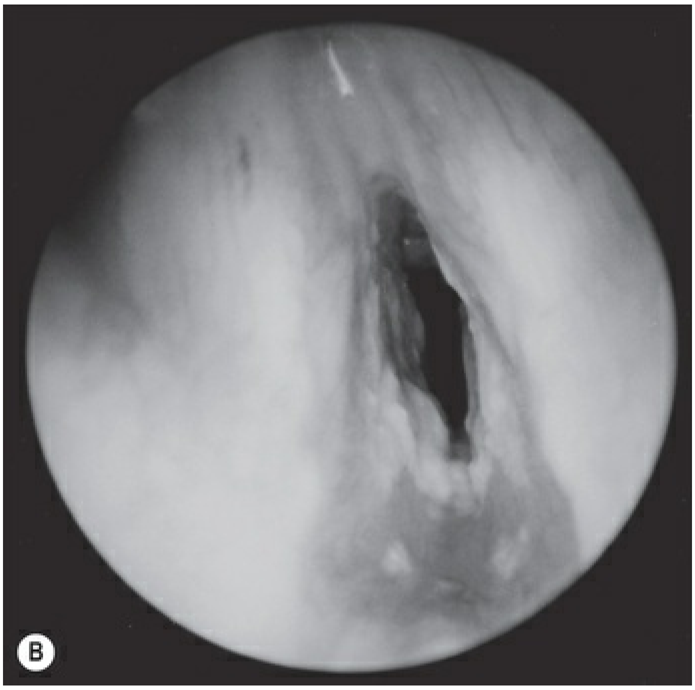


FIGURE 28.4 (A) Lateral neck radiograph of a 22-month-old boy with bacterial tracheitis caused by *Staphylococcus aureus* shows subglottic haziness (similar to croup). (B) Endoscopic view of the trachea shows mucosal denudation, intraluminal debris, and purulent laryngotracheal secretions. (Courtesy of Richard H. Schwartz, MD, Vienna, VA.)

Management.

Proactive airway management is critical in managing bacterial tracheitis to prevent complete airway obstruction and consequent respiratory arrest. In most of the larger published case series, 80% to 100% of patients required intubation or tracheostomy and mechanical ventilation. Intubation usually is challenging and requires the use of an endotracheal tube of considerably smaller diameter than would be expected based on the patient's age. The personnel and equipment for a tracheostomy must be readily available in case conventional intubation fails.

Appropriate empiric antibiotic treatment must include effective antistaphylococcal coverage. A combination of a third-generation cephalosporin (e.g., ceftriaxone, cefotaxime) and a penicillinase-resistant penicillin (e.g., cloxacillin, nafcillin) given intravenously is a suitable choice in areas where community-acquired MRSA infections are unlikely. Otherwise, vancomycin should replace the latter component. Good-quality evidence is lacking, but many centers use systemic corticosteroids in the first few days of the illness with the intention to reduce airway edema.

Most patients require ventilatory support for only 2 to 5 days unless complications occur. The optimal duration of antibiotic treatment is unknown, but most experts recommend a minimum of 10 days of treatment.

Complications and Prognosis.

Complications of bacterial tracheitis include pneumothorax, pneumomediastinum, pulmonary edema, acute respiratory distress syndrome, hypotension, and cardiorespiratory arrest.[230,223,234,238] Cases with concurrent toxic shock syndrome have been described.[230,232,239] Neurologic sequelae are common in patients who experience cardiorespiratory arrest. Subglottic stenosis and subglottic polyps are rare long-term sequelae.[230,240]

Bacterial tracheitis is a potentially life-threatening condition, with some early publications reporting case fatalities in excess of 20%.[230,238] Fatal outcomes have been uncommon in the past decade, likely reflecting improvements in intensive care support.[125,220,221]

Acute Bronchitis

Acute bronchitis predominately occurs in adolescents and adults. Data from the US National Health Interview Survey suggest that approximately 5% of all adults experience one or more episodes of bronchitis per year.[241] The incidence peaks in autumn and winter.[242]

Etiologic Agents.

Most cases of bronchitis are nonbacterial in nature, although no causative organism can be identified in many patients. Viral infections appear to account for most cases.[243,244] Viruses commonly implicated in acute bronchitis include influenza virus, parainfluenza virus, respiratory syncytial virus, rhinovirus, adenovirus, and human metapneumovirus.[243–248] Infection due to bacterial organisms, including *Bordetella pertussis*, *Chlamydophila pneumoniae,* and *Mycoplasma pneumoniae*, is less common.[243–245]

Clinical Manifestations and Management.

Illness typically begins with nonspecific upper respiratory tract infection symptoms, which usually last for a few days. This is followed by a second phase characterized by persistent cough, frequently with sputum production or wheezing, which typically lasts for 1 to 3 weeks.[242,243]

Antibiotic therapy is not routinely indicated for previously healthy people with acute bronchitis.[242,249] A Cochrane review that included nine RCTs showed that antibiotic treatment on average reduced the duration of cough by less than 1 day compared with placebo; adverse effects were significantly more common in the antibiotic-treated patients.[250] The update of this review, which included 17 RCTs, concluded that the benefits of antibiotic treatment in bronchitis were marginal.[251,252] Guidelines for treating acute bronchitis by the American College of Physicians and the American College of Chest Physicians have discouraged the routine use of antibiotics, inhaled bronchodilators, or mucolytic agents.[253,254] However, patients diagnosed with pertussis should receive azithromycin, primarily to limit transmission.[242]
